Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Francis Sorrel Greenspan, M.D. (1920-2016)

The tenth edition of *Greenspan's Basic & Clinical Endocrinology* is dedicated to the memories of four outstanding endocrinologists—Dr. John Baxter, Dr. Claude Arnaud, Dr. Melvin Grumbach, and, most especially, Dr. Francis Greenspan who was responsible for taking the initial steps to assemble this textbook more than thirty years ago. Each of these individuals was an outstanding endocrine scientist and/or clinical endocrinologist in the global endocrine community, and each contributed enormously to the success of this textbook.

Contents

5. The Posterior Pituitary (Neurohypophysis)   121

Alan G. Robinson, MD

6. Growth   137

Dennis Styne, MD

7. The Thyroid Gland   171

David S. Cooper, MD and
Paul W. Ladenson, MD (Oxon)., MD

8. Metabolic Bone Disease   239

Dolores M. Shoback, MD, Anne L. Schafer, MD, and Daniel D. Bikle, MD, PhD

9. Glucocorticoids and Adrenal Androgens 299

**Ty B. Carroll, MD, David C. Aron, MD, MS,
James W. Findling, MD, and J. Blake Tyrrell, MD**

10. Endocrine Hypertension   343

William F. Young, Jr, MD, MSc

11. Adrenal Medulla and Paraganglia   359

Paul A. Fitzgerald, MD

12. Testes   413

Bradley D. Anawalt, MD and
Glenn D. Braunstein, MD

13. Female Reproductive Endocrinology and Infertility   443

Mitchell P. Rosen, MD and Marcelle I. Cedars, MD

14. Disorders of Sex Development   501

Rodolfo A. Rey, MD, PhD,
Christopher P. Houk, MD,
Selma Witchel, MD, and Peter A. Lee, MD, PhD

15. Puberty   547

Dennis Styne, MD

16. The Endocrinology of Pregnancy   575

Bansari Patel, MD, Joshua F. Nitsche, MD, PhD, and Robert N. Taylor, MD, PhD

17. Pancreatic Hormones and Diabetes Mellitus   595

Umesh Masharani, MB, BS, MRCP (UK) and Michael S. German, MD

18. Hypoglycemic Disorders   683

**Umesh Masharani, MB, BS, MRCP (UK),
Stephen E. Gitelman, MD, and Roger K. Long, MD**

19. Disorders of Lipoprotein Metabolism   705

Mary J. Malloy, MD and John P. Kane, MD, PhD

20. Obesity   731

**Alka M. Kanaya, MD and
Christian Vaisse, MD, PhD**

21. Humoral Manifestations of Malignancy   743

Dolores M. Shoback, MD and Janet L. Funk, MD

22. Multiple Endocrine Neoplasia   757

David G. Gardner, MD, MS

23. Transgender Endocrinology   771

**Stephen M. Rosenthal, MD and
Wylie C. Hembree, MD**

24. Endocrine Emergencies   783

David G. Gardner, MD, MS

25. AIDS Endocrinopathies   809

Carl Grunfeld, MD, PhD

Preface

This represents the tenth edition of *Greenspan's Basic & Clinical Endocrinology*—a bittersweet milestone in that it also marks the recent passing of Dr. Francis Greenspan, the originator and namesake of this textbook. Frank's involvement with this textbook will be sorely missed in the years to come. As with each of the previous editions, the individual chapters have been revised and updated to contain the most current information in the field. Our contributors continue to provide comprehensive content in a highly readable format. Chapter 14 (Disorders of Sex Development) has been completely revised and we have added a new chapter dealing with Transgender Endocrinology (Chapter 23). We trust that you have found previous versions of this text useful and informative and that the current version will continue to serve as a valuable tool for the education of your trainees and management of your endocrine patients.

David G. Gardner, MD, MS
Dolores Shoback, MD
San Francisco, CA

Hormones and Hormone Action

Edward C. Hsiao, MD, PhD and David G. Gardner, MD, MS

ACTH	Adrenocorticotropin hormone		**FAD**	Flavin adenine dinucleotide
ACVR1	Activin A receptor, type I		**FGF**	Fibroblast growth factor
AD1	Activation domain 1		**FMN**	Flavin mononucleotide
AD2	Activation domain 2		**FOX A1**	Forkhead transcription factor A1
AF-1	Activator function-1		**FXR**	Farnesoid X-activated receptor
AF-2	Activator function-2		**GAP**	GTPase-activating protein
Akt	Protein kinase B		**GAS**	Interferon gamma activated sequences
AMH	Anti-müllerian hormone		**GDP**	Guanosine diphosphate
ANP	Atrial natriuretic peptide		**GH**	Growth hormone
AP-1	Activator protein-1		**GHR**	Growth hormone receptor
APC	Adenomatous polyposis coli gene		**GLUT4**	Glucose transporter type 4
AR	Androgen receptor		**GR**	Glucocorticoid receptor
β-ARK	β-Adrenergic receptor kinase		**GRB2**	Growth factor receptor–bound protein-2
β-TrCP	Beta-transducin repeats-containing proteins		**GRE**	Glucocorticoid response element
BMP	Bone morphogenetic protein		**GRIP**	Glucocorticoid receptor–interacting protein
BNP	B-type natriuretic peptide		**GSK3**	Glycogen synthase kinase-3
BXR	Benzoate X receptor		**GTF**	General transcription factor
cAMP	Cyclic adenosine-3′,5′-monophosphate		**GTP**	Guanosine triphosphate
CAR	Constitutive androstane receptor		**HRE**	Hormone response element
CARM	Coactivator-associated arginine methyltransferase		**HSP**	Heat shock protein
CBP	CREB-binding protein		**ID**	Receptor–repressor interaction domain
cGMP	Cyclic guanosine-3′,5′-monophosphate		**IGF**	Insulin-like growth factor
CKI	Casein kinase I		**I-κB**	Inhibitor of nuclear factor kappa B
CNP	C-type natriuretic peptide		**IKK**	Inhibitor of nuclear factor kappa B kinase
CREB	cAMP response element-binding protein		IP_3	Inositol 1,4,5-trisphosphate
DAG	Diacylglycerol		IP_4	Inositol 1,3,4,5-tetrakis-phosphate
DAN	Differential screening-selected gene in neuroblastoma		**ISRE**	Interferon-stimulated response element
DBD	DNA-binding domain		**JAK**	Janus kinase
DRIP	Vitamin D receptor–interacting protein		**KHD**	Kinase homology domain
DVL	Dishevelled		**LBD**	Ligand-binding domain
EGF	Epidermal growth factor		**LH**	Luteinizing hormone
ER	Estrogen receptor		**LRP**	Lipoprotein receptor related protein
ERK	Extracellular signal–regulated kinase		**LXR**	Liver X receptor
			MAPK	Mitogen-activated protein kinase

MEK	MAPK kinase		**RAR**	Retinoic acid receptor
MR	Mineralocorticoid receptor		**RE**	Response element
MSH	Melanocyte-stimulating hormone		**RGS**	Regulators of G protein signaling
N-Cor	Nuclear receptor corepressor		**RSK**	Ribosomal S6 kinase
NF-κB	Nuclear factor kappa B		**RXR**	Retinoid X receptor
NO	Nitric oxide		**SH2**	*src* homology domain type 2
NOS	Nitric oxide synthase		**SIE**	Sis-inducible element
NPR	Natriuretic peptide receptor		**SMRT**	Silencing mediator for RXR and TR
NR	Nuclear receptor		**SOCS**	Suppressor of cytokine signaling
NRPTK	Non-receptor protein tyrosine kinase		**SOS**	Son-of-sevenless
PAK	p21-activated kinase		**SOST**	Sclerostin
P/CAF	p300/CBP-associated factor		**SR**	Steroid receptor
P/CIP	p300/CBP cointegrator-associated protein		**SRC**	Steroid receptor coactivator
PDE	Phosphodiesterase		**SRE**	Serum response element
PDGF	Platelet-derived growth factor		**SRF**	Serum response factor
PDK	Phosphatidylinositol-3,4,5 trisphosphate-dependent kinase		**STAT**	Signal transducer and activator of transcription
PHP-1a	Pseudohypoparathyroidism type 1a		**SWI/SNF**	ATP-dependent chromatin remodeling complex
PI-3K	Phosphoinositide-3-OH kinase		**TAZ**	WW domain-containing transcription regulator protein 1
PIP$_2$	Phosphatidylinositol-4,5-bisphosphate		**TBP**	TATA-binding protein
PIP$_3$	Phosphatidylinositol-3,4,5-trisphosphate		**TCF/LEF**	T-cell factor/lymphoid enhancer factor
PI(3,4)P2	Phosphatidylinositol-3,4-bisphosphate		**TGF-β**	Transforming growth factor beta
PKA	Protein kinase A		**TLE**	Transducin-like enhancer protein
PKB	Protein kinase B		**TPA**	12-*O*-tetradecanoyl-phorbol 13-acetate
PKC	Protein kinase C		**TR**	Thyroid hormone receptor
PKG	cGMP-dependent protein kinase		**TRAF**	Tumor necrosis factor receptor–associated factor
PLCβ	Phospholipase C beta		**TRAP**	Thyroid hormone receptor–associated protein
PLCγ	Phospholipase C gamma		**TRE**	TPA response element
PLC$_{PC}$	Phosphatidylcholine-selective phospholipase		**TSH**	Thyroid-stimulating hormone
POL II	RNA polymerase II		**VDR**	Vitamin D receptor
PPAR	Peroxisome proliferator–activated receptor		**Wnt**	int/Wingless family
PR	Progesterone receptor		**YAP**	Yes-associated protein-1
PTH	Parathyroid hormone			
PXR	Pregnane X receptor			
RANK	Receptor activator of nuclear factor kappa B			

Hormones are signaling molecules that traffic information from one point to another, typically through a soluble medium like the extracellular fluid or blood. Hormones fall into one of a number of different hormonal classes (eg, steroids, mono-amines, peptides, proteins, and eicosanoids) and signal through a variety of general (eg, nuclear vs cell surface) and specific (eg, tyrosine kinase vs phosphoinositide turnover) mechanisms in target cells.

Hormones produced in one tissue may promote activity in a target tissue at some distance from the point of secretion (endocrine effect). In this case the hormone travels through the bloodstream, often bound to a plasma protein, to access the target tissue. In addition, hormones may act locally following secretion; either on a neighboring cell (paracrine effect), on the secretory cell itself (autocrine effect), or without actually being released from the secretory cell (intracrine effect) (Figure 1–1).

Identification of a tissue as a target for a particular hormone requires the presence of receptors for the hormone in cells of the target tissue. These receptors, in turn, are linked to effector mechanisms that lead to the physiological effects associated with the hormone.

RELATIONSHIP TO THE NERVOUS SYSTEM

Many features of the endocrine system, such as the use of ligands and receptors to communicate between cells, are also found in the nervous system. In fact, from a functional standpoint, the two
FIGURE 1–1 Actions of hormones and neurotransmitters. Endocrine and neurotransmitter cells synthesize hormones and release them by specialized secretory pathways or by diffusion. Hormones can act at the site of production either following release (autocrine) or without release (intracrine) from the producer cell. They can also act on neighboring target cells, including neurotransmitter-producing cells, without entering the circulation (paracrine). Finally, they can access target cells through the circulation (endocrine). Neurotransmitters that access the extracellular compartment, including circulating plasma, can act as paracrine or endocrine regulators of target cell activity (H, hormone; N, neurotransmitter; R, receptor).

systems are probably related evolutionarily. However, there are some important differences between the two systems. While the nervous system uses a highly compartmentalized, closed system of axons and dendrites to connect cells at some distance from one another, the endocrine system relies on circulating plasma to carry newly released hormones to their distant targets. As a result, the time constants for signal delivery are quite different between the two—virtually instantaneous for the nervous system but delayed, by virtue of circulation times, for the endocrine system. Thus, while neural responses are typically measured in seconds, endocrine responses are often measured in minutes to hours—thereby accommodating different needs in the organism. A second difference relates to the nature of the ligand–receptor interaction. In the nervous system, the affinity of receptor for ligand tends to be relatively low. This allows for rapid dissociation of ligand from receptor and, if that ligand is degraded locally, a rapid cessation of biological effect. Despite this rapid dissociation, the secretory neuron is able to maintain receptor occupancy by keeping concentrations of the ligand high around the target

neuron. It does this through pulsatile release of secretory granules into an incredibly small volume (ie, that determined by the volume in the synaptic cleft).

The endocrine system, on the other hand, has a very large volume of distribution for many of its ligands (eg, circulating blood volume). Maintaining ligand concentrations analogous to those present in the synaptic cleft would require prodigious secretory capacity. The endocrine system circumvents this problem by using ligand–receptor interactions with 100-10,000 fold higher binding affinity than those used in the nervous system. In effect, the nervous system is structured to deliver high ligand concentrations to relatively low-affinity receptors, allowing it to activate and inactivate biological effects quickly and in a relatively well-defined topography. Its effects are short lived. In contrast, the endocrine system uses high-affinity receptors to extract and retain ligand from a relatively "dilute" pool in circulating plasma. Its biological effects are long lasting. It has sacrificed rapid response to accommodate a wider area of signal distribution and prolongation of the biological effect. Thus, the systems are not only related but

complementary in the respective roles that they play in normal physiological function.

CHEMICAL NATURE OF HORMONES

Hormones vary widely in terms of their chemical composition. Specific examples include proteins (eg, adrenocorticotrophin), peptides (eg, vasopressin), monoamines (eg, norepinephrine), amino acid derivatives (eg, triiodothyronine), steroids (eg, cortisol), and lipids (eg, prostaglandins). Proteins can be glycosylated (eg, thyroid-stimulating hormone) and/or dimerized (eg, follicle-stimulating hormone) to generate full biological activity. In general, protein, peptide, monoamine, and lipophilic hormones tend to exert their effects primarily through protein receptors at the cell membrane, while thyroid hormone and steroids tend to operate in the cell nucleus. However, exceptions to these rules are being recognized (eg, triiodothyronine activates classic thyroid hormone receptors in the nuclear compartment and the trace amine receptor [TAR1] on the cell surface) and estradiol appears to activate both nuclear and plasma membrane receptors. It is likely that the biological "effect" of a given hormone reflects a composite of receptor activity located in several different cellular compartments.

ENDOCRINE GLANDS AND TARGET ORGANS

Endocrine glands are traditionally defined as ductless glandular structures that release their hormonal secretions into the extracellular space where they can eventually access circulating plasma. Classic endocrine glands include organs like the pituitary gland, thyroid gland, parathyroid glands, pancreatic islets, adrenal glands, ovaries, and testes. It is now clear that hormones can be secreted from nontraditional endocrine organs and play critical roles in the regulation of physiological homeostasis. Examples of the latter include the heart (natriuretic peptides), kidney (erythropoietin and renin), adipose tissue (leptin and adiponectin), bone (osteocalcin), and gut (cholecystokinin and incretins). Once in the circulation, hormones bind to receptors on target tissues to elicit their biological effects. Target tissues for some hormones (eg, glucocorticoids) are numerous, reflecting the ubiquitous distribution of their receptors, while those for other tissues have a more limited distribution (eg, androgens).

REGULATION OF HORMONE LEVELS IN PLASMA

Hormone levels in plasma determine the effective ligand concentration at the level of the hormone receptors in peripheral target cells. Thus, regulation of hormone levels plays an important role in the control of the biological effects that the hormone exerts.

Hormone Biosynthesis

New hormone synthesis is one of the principal mechanisms used to raise hormone levels in circulating plasma. In the case of protein or peptide hormones this usually reflects increased expression of the gene encoding the hormone (ie, increased production of the mRNA encoding the hormone) with subsequent increases in hormone synthesis. In the case of steroid or thyroid hormones it reflects increased sequestration of precursors for hormone synthesis (eg, cholesterol for steroid hormones or iodide for thyroid hormone) as well as increased activity of enzymatic proteins responsible for executing the individual catalytic events required for hormone production. The latter may involve a rate-limiting step in the synthetic cascade (eg, 1-alpha hydroxylase activity in the synthesis of 1,25-dihydroxyvitamin D).

Precursor Processing

Processing of hormone precursors contributes to varying degrees in controlling circulating hormone levels. Most peptide and protein hormones require some processing to generate the mature hormonal product (eg, conversion of proinsulin to insulin) and impairment in the processing activity can alter the ratio of precursor to product in plasma. In other cases, a critical processing event is part of the secretory process itself (eg, cleavage of thyroxine from thyroglobulin) and impaired processing can result in a dramatic reduction in immunoreactivity as well as bioactivity of the mature hormone. In addition, protein hormones may require post-translational modification (eg, glycosylation) or assembly (eg, heterodimerization) prior to secretion in order to optimize biological activity.

Hormone Release

Many hormones (eg, peptides, proteins, and monoamines) are stored in secretory granules in endocrine cells. Release of these granules is promoted by signaling events triggered by exogenous regulators termed secretagogues. This often requires activation of a second messenger system (see discussion under Receptors) like cyclic AMP generation or intracellular calcium mobilization in the endocrine cell. Steroid hormones, on the other hand, are not stored to a significant degree in the hormone-producing cells. In this case synthesis rather than hormone release appears to play the dominant role in controlling hormone levels in circulating plasma.

Hormone Binding in Plasma

Hormones in plasma can circulate either in a free form, uncomplexed with other molecules, or bound to other molecules like plasma proteins. It is the uncomplexed or free form of the hormone that represents the biologically active fraction of hormone in the plasma compartment, and it is this fraction which homeostatic regulatory mechanisms work to preserve.

However, binding of hormone to plasma proteins plays an important role in endocrine physiology. First, it provides a reservoir of hormone that exchanges with the free hormone fraction according to the laws of mass action (see under Receptors). This makes plasma hormone concentrations less dependent on hormone synthesis and release, effectively stabilizing those concentrations over extended periods of time. This also helps guarantee a uniform distribution of hormone concentration in capillary beds
FIGURE 1–2 Role of plasma binding in delivery of hormones to peripheral tissues. Example shows a hormone that is bound (small red circles) to a plasma protein (large circles) and a hormone that is not protein bound (small orange circles). With the bound hormone, only the free fraction is available for tissue uptake. As the free fraction is depleted, additional hormone dissociates from the plasma-binding protein, making hormone available to more distal portions of the tissue. In contrast, all hormones that are not protein bound are quickly extracted in the proximal part of the tissue.

perfusing target tissues (Figure 1–2). Second, it slows the metabolism or turnover of the hormone by sequestering it away from degradative enzymes or filtration by the kidney.

Hormone Metabolism

Metabolism of hormones also plays an important role in regulating hormone concentrations. In some cases metabolism is responsible for converting precursors with less hormonal activity to products with greater activity (eg, conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, or conversion of androstenedione to testosterone). In other cases, metabolism leads to degradation and inactivation of the hormone with a cessation of hormone activity. This type of degradation is often specific to the hormonal class under examination. Steroids, for example, are catalytically converted to inactive metabolites and/or sulfated to promote excretion. Thyroid hormones are subjected to deiodination which strips them of their biological activity. Protein and peptide hormones are internalized by target, as well as nontarget, cells and degraded in intracellular lysosomes. In general, the more avid the degradative mechanisms, the shorter the plasma half-life of the hormone.

Regulation of Hormone Levels

Hormone levels can be modulated through regulatory factors affecting any of the steps listed earlier; however, the bulk of the acute "fine-tuning" of hormone levels occurs at the level of hormone secretion and synthesis. Many, if not most, hormone levels are controlled either directly or indirectly by the biological activity that they serve to control. For example, parathyroid hormone (PTH) secretion, which responds to low extracellular calcium levels, mobilizes calcium out of bone which, in turn, signals back to the parathyroid gland to turn off additional PTH secretion. This negative feedback loop is a hallmark of endocrine regulation. The end product or negative regulator can either be an inorganic ion or metabolite (eg, calcium for PTH) or a hormonal product in the endocrine cascade (eg, thyroid hormone for TSH). Not all feedback is negative in nature. Positive feedback loops (eg, mid-cycle estradiol-induced luteinizing hormone secretion) also play important roles in governing physiological homeostasis.

HORMONE ACTION

Hormones produce their biologic effects through interaction with high-affinity receptors that are, in turn, linked to one or more effector systems within the cell. These effectors involve many different components of the cell's metabolic machinery, ranging from ion transport at the cell surface to stimulation of the nuclear transcriptional apparatus. Steroids and thyroid hormones exert their effects in the cell nucleus, although regulatory activity in the extranuclear compartment has also been documented. Peptide hormones and neurotransmitters, on the other hand, trigger a plethora of signaling activity in the cytoplasmic and membrane compartments while at the same time exerting parallel effects on the transcriptional apparatus. The discussion that follows will focus on the primary signaling systems employed by selected hormonal agonists and attempt to identify examples where aberrant signaling results in human disease.

RECEPTORS

The biologic activity of individual hormones is dependent on their interactions with specific high-affinity receptors on the surfaces or in the cytoplasm or nuclei of target cells. The receptors, in turn, are linked to signaling effector systems responsible for generating the observed biologic responses. Receptors, therefore, convey not only specificity of the response (ie, cells lacking receptors lack responsiveness to the hormone) but also the means for activating the effector mechanism. In general, receptors for the peptide hormones and neurotransmitters are aligned on the cell surface and those for the steroid hormones, thyroid hormone, and vitamin D are found in the cytoplasmic or nuclear compartments, although, as noted earlier, exceptions have been identified in both cases.

Interactions between the hormone ligand and its receptor are governed by the laws of mass action:

$$[H]+[R] \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} [HR]$$
where $[H]$ is the hormone concentration, $[R]$ is the receptor concentration, $[HR]$ is the concentration of the hormone–receptor

complex, and k_{+1} and k_{-1} are the rate constants for [HR] formation and dissociation, respectively. Thus, at equilibrium,

$$k_{+1}[H][R] = k_{-1}[HR]$$

or

$$\frac{[H][R]}{[HR]} = \frac{k_{-1}}{k_{+1}} = K_D$$

where K_D is the equilibrium dissociation constant that defines the affinity of the hormone–receptor interaction (ie, lower the dissociation constant, higher the affinity). Assuming that total receptor concentration R_0 = [HR] + [R], this equation can be rearranged to give

$$\frac{[HR]}{[H]} = -\left(\frac{[HR]}{K_D}\right) + \frac{R_0}{K_D}$$

This is the Scatchard equation and states that when bound ligand over free ligand (ie, [HR]/[H]) is plotted against bound ligand (ie, [HR]), the slope of the line is defined by $-1/K_D$, the y-intercept by R_0/K_D, and the x-intercept by R_0 (Figure 1–3). When [HR] = $R_0/2$, [H] = K_D; therefore, the K_D is also the concentration of hormone [H]
FIGURE 1–3 Ligand saturation (A) and Scatchard analysis (B) of a hypothetical hormone receptor interaction. K_D represents the dissociation constant; R_0 the total receptor concentration; [HR] and [H] the bound and free ligand, respectively. Note in (A) that the K_D is the concentration [H] at which half of available receptors are occupied.

at which one-half of the available receptors are occupied. Thus, knowledge of bound and free ligand concentrations, which can be determined experimentally, provides information regarding the affinity of the receptor for its ligand and the total concentration of receptor in the preparation.

Agents that bind to receptors with high affinity are classified as either agonists or antagonists based on the functional outcome of this receptor–ligand interaction. Agonists are ligands that trigger the effector mechanisms and produce biologic effects. Antagonists bind to the receptor but do not activate the effector mechanisms. Because they occupy receptor and block association with the agonist, they antagonize the functional activity of the agonist. Partial agonists bind to the receptor but possess limited ability to activate the effector mechanisms. In different circumstances, partial agonists may demonstrate variable biologic activity. For example, when used alone, they may display weak activating activity, whereas their use together with a full agonist may lead to inhibition of function because the latter is displaced from the receptor molecule by a ligand with lower intrinsic activity.

In some systems, receptors are available in surplus, which may be several-fold higher than that required to elicit a maximal biologic response. Although such spare receptor systems superficially appear redundant, they are designed to rectify a mismatch between low circulating ligand levels and a relatively low-affinity ligand–receptor interaction. Thus, by increasing the number of available receptors, the system is guaranteed a sufficient number of ligand-bound receptor units to activate downstream effector systems fully, despite operating at subsaturating levels of ligand.

NEUROTRANSMITTER AND PEPTIDE HORMONE RECEPTORS

As mentioned earlier, neurotransmitter and peptide hormones interact predominantly with receptors expressed on the plasma membrane at the cell surface. The K_D of a neurotransmitter for its receptor is typically higher than that of a hormone for its receptor, reflecting a higher k_{off} rate constant (see earlier). Neurotransmitter receptor occupancy is driven by the extraordinarily high concentrations of ligand that can be achieved in the synaptic cleft, and occupancy of the hormone receptor is driven by its high affinity for ligand. The high k_{off} of the neurotransmitter–receptor interaction guarantees that the effect is rapid in onset but of short duration, whereas the lower k_{off} of the hormone–receptor interaction guarantees that the effect is slow in onset but difficult to extinguish, kinetics that are more appropriate for the hormonal functions of these ligands.

The neurotransmitter and peptide receptors can be divided into several major groups (Table 1–1 and Figure 1–4). The first includes the so-called serpentine or "seven-transmembrane-domain" receptors. These receptors each contain an amino terminal extracellular domain followed by seven hydrophobic amino acid segments, each of which is believed to span the membrane bilayer (see Figure 1–4). The seventh of these, in turn, is followed by a hydrophilic carboxyl terminal domain that resides within the cytoplasmic compartment. As a group, they share a dependence

on the G protein transducers (GPCRs discussed later) to execute many of their biologic effects. A second group includes the single-transmembrane-domain receptors that harbor intrinsic tyrosine kinase activity. This includes the insulin, insulin-like growth factor (IGF), and epidermal growth factor (EGF) receptors. A third group, which is functionally similar to the second group, is characterized by a large, extracellular binding domain followed by a single membrane-spanning segment and a cytoplasmic tail. These receptors do not possess intrinsic tyrosine kinase activity but appear to function through interactions with soluble transducer molecules which do possess such activity. Prolactin and growth hormone are included in this group. A fourth group is the transforming growth factor beta (TGF-β) family which signals through serine/threonine kinase domains in their cytoplasmic tails. A fifth group, which includes the natriuretic peptide receptors, operates through activation of a particulate guanylyl cyclase and synthesis of cGMP. The cyclase is covalently attached at the carboxyl terminal portion of the ligand-binding domain (LBD) and thus represents an intrinsic part of the receptor molecule.

G PROTEIN–COUPLED RECEPTORS

G protein–coupled receptors (GPCRs) constitute a large superfamily of molecules capable of responding to ligands of remarkable structural diversity—ranging from photons to large polypeptide hormones. Because of their diversity, GPCRs are the target of over 40% of modern pharmaceuticals. GPCRs initiate
FIGURE 1–4 Structural schematics of different classes of membrane-associated hormone receptors. Representative ligands are presented in parentheses (ANP, atrial natriuretic peptide; EGF, epidermal growth factor; GH, growth hormone; TGF-β, transforming growth factor beta).

intracellular signaling by activating one (or in some cases multiple) G proteins resulting in biological responses. These receptors share overall structural features, most notably seven membrane-spanning regions connected by intracellular and extracellular loops (see Figure 1–4). The receptors are oriented such that the amino terminal domain is extracellular, whereas the carboxyl terminal tail is cytoplasmic. The membrane-spanning segments interact with one another, forming an irregular cylindrical bundle around a central cavity within the molecule. GPCRs can assume at least two conformations with differing orientations of the

membrane-spanning segments relative to one another. One orientation is favored in the absence of an agonist ligand. In this orientation the receptor does not activate a G protein (inactive conformation). The second orientation is stabilized by the binding of an appropriate agonist ligand. In this conformation the receptor activates a cognate G protein (active conformation). All GPCRs are thought to undergo a similar conformational switch on agonist binding, producing a structural change in the cytoplasmic domain that promotes G protein activation. Some small agonists, such as catecholamines, are able to enter the cavity formed by the transmembrane segments, thereby directly stabilizing the active receptor conformation. Other agonists, such as large polypeptide hormones, bind primarily to the extracellular domain of their GPCRs. More recently, a number of orphan GPCRs have been found to be activated by hydrophobic ligands including steroids (eg, estrogen binding to GPR30) and lipids (eg, LPA binding to GPR23). Ligand binding indirectly results in movement of the transmembrane region of the receptor and stabilization of the active receptor conformation.

Until recently, it was thought that GPCRs function exclusively as monomers. Many GPCRs are now known to dimerize either with themselves (homodimerization) or with other GPCRs (heterodimerization). In some cases, dimerization is important for efficient receptor biosynthesis and membrane localization. In other cases, dimerization is important for optimal ligand affinity, specificity, or receptor signaling.

Heritable mutations in a variety of GPCRs are known to be associated with disease. Loss-of-function phenotypes can result from mutations that eliminate one or both receptor alleles, or that result in the synthesis of signaling-defective receptors. Gain-of-function phenotypes generally result from point mutations that produce constitutively active receptors (ie, stably assume the active receptor conformation even in the absence of an agonist ligand). Examples of such GPCR disorders relevant to endocrinology are described later and discussed in greater detail elsewhere in this book.

G PROTEIN TRANSDUCERS

G proteins are a family of heterotrimeric proteins that regulate the activity of effector molecules (eg, enzymes, ion channels) (examples in Table 1–2), ultimately resulting in biological responses. The identity of a G protein is defined by the nature of its α subunit, which is largely responsible for effector activation. The major G proteins involved in hormone action (and their actions on effectors) are G_s (stimulation of adenylyl cyclase), G_i (inhibition of adenylyl cyclase; regulation of calcium and potassium channels), and $G_{q/11}$ (stimulation of phospholipase C [PLC] β). Recently, GPCRs linked to $G_{12/13}$ were identified as key inputs of the Hippo/YAP/TAZ transcriptional regulators, which play a central role in controlling organ size, growth, and integrating extracellular cues. In each of these cases, the β and γ subunits of G proteins are tightly associated with one another and function as a dimer. In some cases, the $\beta\gamma$ subunit dimer can also regulate effector function.

TABLE 1–2 G protein subunits selectively interact with specific receptor and effector mechanisms.

G Protein Subunit	Representative Associated Receptors	Effector
α_s	β-Adrenergic TSH Glucagon	Adenylyl cyclase Ca^{2+} channels K^+ channels
α_i	α_2-Adrenergic Muscarinic (type II)	Adenylyl cyclase Ca^{2+} channels K^+ channels
α_q	α_1-Adrenergic	PLCβ
β/γ		Adenylyl cyclase (+ or −) PLC Supports βARK-mediated receptor phosphorylation and desensitization

G proteins are noncovalently tethered to the plasma membrane and are thus proximate to their cognate receptors and to their effector targets. The basis for specificity in receptor–G protein interactions has not been fully defined. It is likely that specific structural determinants presented by the cytoplasmic loops of the GPCR determine the identity of the G proteins that are activated. It is the nature of the α subunit of the G protein that is critical for receptor signaling. There are about a dozen different G protein α subunits and hundreds of distinct GPCRs.

Clearly, each specific G protein can be activated by a large number of different receptors. For example, G_s is activated by receptors for ligands as diverse as β-adrenergic catecholamines and large polypeptide hormones such as luteinizing hormone (LH). LH is thereby able to stimulate adenylyl cyclase and raise intracellular levels of cAMP in cells that express LH receptors (eg, Leydig cells of the testis). In contrast, an individual GPCR can couple to multiple Gα subunits, often in response to different ligands (eg, PTH receptor can activate G_s, G_i, and G_q).

Figure 1–5 is a schematic representation of the molecular events associated with activation of G proteins by GPCRs. In the basal, inactive state, the G protein is an intact heterotrimer with guanosine diphosphate (GDP) bound to the α subunit. Agonist binding to a GPCR promotes the physical interaction between the receptor and its cognate G protein. This produces a conformational change in the G protein, resulting in the dissociation of GDP. This in turn allows the binding of GTP (which is present at a much higher concentration in cells than is GDP) to the α subunit. Dissociation of the GTP-bound α subunit from the $\beta\gamma$ dimer then occurs, allowing these subunits to activate their effector targets. Dissociation of the hormone–receptor complex also occurs. The duration of activation is determined by the intrinsic GTPase activity of the G protein α subunit. Hydrolysis of GTP to GDP terminates the activity and promotes reassociation of the $\alpha\beta\gamma$ trimer, returning the system to the basal state. The GTPase activity of G protein α subunits can be increased by the action of proteins termed "regulators of G protein signaling" (RGS proteins) which act by increasing the speed of GTP cycling.
FIGURE 1–5 G protein–mediated signal transduction. α and β/γ subunits of a representative G protein are depicted (see text for details) (E, effector; H, hormonal ligand; R, hormone receptor).

EFFECTORS

Numerous effectors have been linked to the GPCRs. A number of these are presented in Table 1–2. A great many other G proteins—not dealt with here—are coupled to physical or biochemical stimuli but have very limited involvement in hormone action. As discussed, adenylyl cyclase, perhaps the best studied of the group, is activated by G_s (Figure 1–6). This activation results in a transient increase in intracellular cAMP levels. The cAMP binds to the inhibitory regulatory subunit of inactive protein kinase A (PKA) and promotes its dissociation from the complex, thereby permitting enhanced activity of the catalytic subunit. The latter phosphorylates a variety of cellular substrates, among them the hepatic phosphorylase kinase that initiates the enzymatic cascade which results in enhanced glycogenolysis. It also phosphorylates and activates the cAMP response element–binding protein (CREB), which mediates many of the known transcriptional responses to cAMP (and to some extent calcium) in the nuclear compartment. Other transcription factors are also known to be phosphorylated by PKA.

PLC beta (PLCβ) is a second effector system that has been studied extensively. The enzyme is activated through G_q-mediated
FIGURE 1–6 β-Adrenergic receptor/G_s mediated signaling in the cytoplasmic and nuclear compartments. The cAMP response element–binding protein (CREB) is depicted bound to a consensus CRE in the basal state. Phosphorylation of this protein leads to activation of the juxtaposed core transcriptional machinery.

transduction of signals generated by a wide array of hormone–receptor complexes, including those for angiotensin II, α-adrenergic agonists, and endothelin. Activation of the enzyme leads to cleavage of phosphoinositol 4,5-bisphosphate in the plasma membrane to generate inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) (Figure 1–7). The former interacts with a specific receptor present on the endoplasmic reticulum membrane to promote release of Ca^{2+} into the cytoplasmic compartment. The increased calcium, in turn, may activate protein kinases, promote secretion, or foster contractile activity. Depletion of intracellular calcium pools by IP_3 results in enhanced uptake of calcium across the plasma membrane (perhaps through generation of IP_4 [1,3,4,5-tetrakisphosphate]), thereby activating a second, albeit indirect, signaling mechanism that serves to increase intracellular calcium levels even further. DAG functions as an activator of several protein kinase C (PKC) isoforms within cells. Several different isoforms of PKC (eg, α, β, γ) may exist in a given cell type. A number of these are calcium-dependent, a property which, given the IP_3 activity mentioned earlier, provides the opportunity for a synergistic interaction of the two signaling pathways driven by PLCβ activity.

However, not all PKC activity derives from the breakdown of PIP_2 substrate. Metabolism of phosphatidylcholine by PLC_{PC} (phosphatidylcholine-selective phospholipase) leads to the generation of phosphocholine and DAG. This latter pathway is believed to be responsible for the more protracted elevations in PKC activity seen following exposure to agonist.

Other phospholipases may also be important in hormone-dependent signaling. Phospholipase D employs phosphatidylcholine as a substrate to generate choline and phosphatidic acid. The latter may serve as a precursor for subsequent DAG formation. As with PLC_{PC} earlier, no IP_3 is generated as a consequence of this reaction. Phospholipase A_2 triggers release of arachidonic acid, a precursor of prostaglandins, leukotrienes, endoperoxides, and thromboxanes, all signaling molecules in their own right. The relative contribution of these other phospholipases to hormone-mediated signal transduction and the role of the specific lipid breakdown products (eg, phosphocholine, phosphatidic acid) in conveying regulatory information remains an area of active research.

Activation of effectors by GPCRs is subject to regulatory mechanisms that prevent overstimulation of cells by an agonist
FIGURE 1–7 PLCβ-coupled receptor/G_q mediated signaling in the cytoplasmic and nuclear compartments (DAG, diacylglycerol; PC, phosphatidylcholine; PKC, protein kinase C; PLC, phospholipase).
FIGURE 1–8 Kinase-dependent desensitization of the ligand–receptor complex. Schema shown is that for the β-adrenergic receptor, but similar systems probably exist for other types of G protein–linked receptors (ACa, active adenylyl cyclase; ACi, inactive adenylyl cyclase; β-ARK, β-adrenergic receptor kinase; PKA, protein kinase A).

ligand. At the level of the receptor, two regulatory events are known to occur. One is desensitization, wherein initial stimulation of a receptor by its agonists leads to a loss of the ability of the receptor to subsequently elicit G protein activation. This is shown schematically in Figure 1–8 for the β-adrenergic receptor. A similar regulatory mechanism exists for many other GPCRs. Agonist binding to the receptor produces G protein activation and results also in activation of a kinase (termed G protein–coupled receptor kinase, GRK) that phosphorylates the cytoplasmic domain of the receptor. By virtue of this phosphorylation, the receptor acquires high affinity for a member of the arrestin family of proteins. The name "arrestin" derives from the observation that the receptor is no longer capable of interacting with a G protein when arrestin is bound. Thus, the phosphorylated receptor becomes uncoupled from its G protein, preventing signaling to the effector. The receptor remains inactive until a phosphatase acts to restore the receptor to its unphosphorylated state thus releasing the bound arrestin. Recently, β arrestin-dependent signaling pathways have been identified where the arrestins can link GPCRs to intracellular signaling such as the MAPK cascades. Beta arrestins also appear to act directly as signal transducers by interacting with regulators of transcription factors. This receptor-independent signaling capacity likely has implications for endocrine diseases including those affecting bone.

Many GPCRs are also susceptible to agonist-induced down-regulation, resulting in a reduced level of cell surface receptors following exposure of cells to an agonist. This can result from agonist-induced internalization of receptors, followed by trafficking of receptors to lysosomes where degradation occurs. In addition, chronic exposure of cells to an agonist may result in signaling events that suppress the biosynthesis of new receptors, thereby lowering steady-state receptor levels. Together, these regulatory events ensure that the cell is protected from excessive stimulation in the presence of sustained high levels of an agonist.

Recently, it has become clear that these events serving to dampen G protein signaling can also have important roles in promoting cell signaling. For example, arrestin association with GPCRs can activate specific pathways such as the MAP kinase pathway independently of G protein signaling. In addition, internalized GPCRs can, in some cases, retain the ability to signal, and the effects may differ from those produced when activation occurs at the plasma membrane.

DISORDERS OF G PROTEINS AND G PROTEIN–COUPLED RECEPTORS

Two bacterial toxins are capable of covalently modifying specific G protein α subunits, thereby altering their functional activity. Cholera toxin is a protein that binds to receptors present on all cells, resulting in the internalization of the enzymatic subunit of the toxin. The toxin enzyme is an ADP-ribosyl transferase that transfers ADP-ribose from NAD to an acceptor site (Arg^{201}) on the α subunit of G_s. This covalent modification greatly inhibits the GTPase activity of α_s, enhancing the activation of adenylyl cyclase by extending the duration of the active GTP-bound form of the G protein. Even in the absence of an active GPCR, GDP dissociates (albeit very slowly) from the G protein. Thus, cholera toxin will eventually activate adenylyl cyclase activity even without agonist binding to a GPCR. The result is a large and sustained activation of adenylyl cyclase. When this occurs in intestinal epithelial cells,

the massive increase in cAMP results in the increased water and salt secretion into the gut that is characteristic of cholera.

Pertussis toxin is also an ADP-ribosyl transferase. However, in this case, the substrates are α subunits of different G proteins, most notably G_i and G_o. The ADP-ribose moiety is transferred to a cysteine residue near the carboxyl terminus of the α subunit, a region required for interaction with activated GPCRs. Once ADP-ribosylated by pertussis toxin, these G proteins are no longer able to interact with activated receptors and are thus stuck in an inactive (GDP-bound) conformation. Inhibition of receptor-mediated activation of G_i and G_o accounts for many of the clinical manifestations of pertussis infection.

Genetic mutations in G protein α subunits are seen in a number of human diseases. Acquired activating mutations in $G\alpha_s$ can produce a variety of phenotypes depending on the site of expression of the mutant protein. In McCune-Albright syndrome, the mutation occurs in a subset of neural crest cells during embryogenesis. All of the descendants of these cells, including certain osteoblasts, melanocytes, and ovarian or testicular cells, express the mutant protein. The result is a form of genetic mosaicism in which the consequence of unregulated production of cAMP in particular tissues is evident (ie, the progressive bone disorder polyostotic fibrous dysplasia, the abnormal skin pigmentation referred to as café au lait spots, and gonadotropin-independent precocious puberty). In cells where cAMP is linked to cell proliferation (eg, thyrotropes, somatotropes), a subset of patients with benign tumors has been shown to have acquired activating mutations in $G\alpha_s$. Activating mutations in $G\alpha_{i2}$, which is coupled to cell proliferation, have been reported in a subset of adrenal and ovarian tumors.

Loss-of-function mutations in $G\alpha_s$ are associated with the hereditary disorder pseudohypoparathyroidism type 1 (PHP-1a). This disorder, first described by Fuller Albright, was the first documented example of a human disease attributable to target cell resistance to a hormone. Affected patients display biochemical features of hypoparathyroidism (eg, hypocalcemia, hyperphosphatemia) but have markedly increased circulating levels of PTH and display target cell resistance to PTH. Many hormone receptors couple to adenylyl cyclase via $G\alpha_s$, yet patients with PHP-1a generally display only subtle defects in responsiveness to other hormones (eg, TSH, LH). The explanation for this lies in the fascinating genetics of this disorder. In brief, affected patients have one normal and one mutated $G\alpha_s$ allele. The mutated allele fails to produce an active form of the protein. Tissues in these patients are expected to express about 50% of the normal level of $G\alpha_s$, a level sufficient to support signaling to adenylyl cyclase. However, in certain tissues, the α_s gene is subject to genetic imprinting such that the paternal allele is expressed poorly or not at all. In individuals harboring inactivating mutations, if the paternal allele has the mutation, all cells express about 50% of the normal level of $G\alpha_s$ (derived from the normal maternal allele). However, if the maternal allele has the mutation, then the cells in which paternal imprinting occurs express low levels or no $G\alpha_s$. One of the major sites of this paternal imprinting is in the proximal renal tubule, an important target tissue for the physiologic actions of PTH. This accounts for the clinical resistance to PTH seen in PHP-1a and accounts also for the fact that only a subset of patients

with haploinsufficiency of α_s are resistant to PTH. Interestingly, essentially all patients with haploinsufficiency of $G\alpha_s$ display Albright hereditary osteodystrophy, a developmental disorder with phenotypic manifestations affecting a variety of tissues. This indicates that even a partial loss of adenylyl cyclase signaling is incompatible with normal development.

Mutations in the genes encoding GPCRs are being increasingly recognized as important in the pathogenesis of endocrine disorders. Loss-of-function mutations generally need to be homozygous (or compound heterozygous) in order to result in a significant disease phenotype. This is probably due to the fact that most cells express higher levels of each receptor, above what is needed for maximal cellular response (spare receptors). Thus, a 50% reduction in the amount of a cell surface receptor may have little influence on the ability of a target cell to respond. However, in some situations, haploinsufficiency of a GPCR can produce a clinical phenotype. For instance, heterozygous loss-of-function mutations in the G protein–coupled calcium-sensing receptor results in the autosomal dominant disorder familial hypocalciuric hypercalcemia type 1 due to usually mild dysregulation of PTH secretion and renal calcium handling. Homozygous loss-of-function of the calcium-sensing receptor results in severe neonatal hyperparathyroidism due to the loss of the ability of plasma calcium to suppress PTH secretion and promote renal calcium clearance. Syndromes of hormone resistance have also been reported in patients lacking expression of functional GPCRs for vasopressin, ACTH, and TSH. Loss of functional expression of the PTH receptor results in Blomstrand chondrodysplasia, a disorder that is lethal due to the inability of PTH-related protein (a PTH receptor agonist) to promote normal cartilage development.

Mutations that render GPCRs constitutively active (in the absence of an agonist ligand) are seen in a number of endocrine disorders. Generally speaking, such mutations produce a disease phenotype resembling that seen with excessive levels of the corresponding hormone agonist. Thus, activating mutations in the TSH receptor produce neonatal thyrotoxicosis, and activating mutations in the LH receptor result in pseudoprecocious puberty or testotoxicosis. Activating mutations in the PTH receptor result in Jansen-type metaphyseal chondrodysplasia; a disorder characterized by hypercalcemia and increased bone resorption (mimicking the effects of excess PTH on bone) and delayed cartilage differentiation (mimicking the effects of excess PTH-related protein on cartilage). An approach to treating disorders resulting from constitutively active GPCRs would be administration of "inverse agonists," agents that stabilize receptors in their inactive conformation. Although inverse agonists have been identified for a number of GPCRs, they have yet to be successfully employed as therapeutics. In contrast, molecular mimics of endogenous ligands have found utility as a way to stimulate signaling *via* allosteric receptor changes. This is the basis for cinacalcet's activity as a calcimimetic on the calcium-sensing receptor in the parathyroid cell and accounts for its utility in treating secondary hyperparathyroidism. Finally, molecular analysis of GPCRs has revealed that point mutations, in addition to producing constitutive activity, can alter the specificity of ligand binding or the ability of the receptor to become desensitized. It is almost certain that such mutations will be found to provide the basis for some more subtle endocrinopathies.

GROWTH FACTOR RECEPTORS

The growth factor receptors differ from those described earlier both structurally and functionally. Unlike the GPCRs, the growth factor receptors span the membrane only once and acquire their signaling ability, at least in part, through activation of tyrosine kinase activity, which is intrinsic to the individual receptor molecules. The insulin and IGF receptors fall within this group, as do those for the autocrine or paracrine regulators platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), and EGF. Signaling is initiated by the association of ligand (eg, insulin) with the receptor's extracellular domain (Figure 1–9) and subsequent
FIGURE 1–9 Signaling by a tyrosine kinase–containing growth factor receptor. Receptors depicted here as monomers for simplicity; typically dimerization of receptors follows association with ligand. Autophosphorylation of one or more critically positioned tyrosine residues in the receptor leads to association with accessory proteins or effectors through SH2 domains present on the latter. In some cases, an SH3 domain present on the same protein leads to recruitment of yet other proteins leading to further complex assembly.

receptor dimerization. The duration of signaling can be regulated by clathrin, a protein that is required for cellular endocytosis. Internalization of the ligand/receptor complex results in phosphorylation of tyrosines both on the receptor itself as well as on nonreceptor substrates. It is assumed that phosphorylation of these substrates results in a cascade of activation events, similar to those described for the G protein–coupled systems, which contribute to perturbations in intracellular pathways. The autophosphorylation of the receptor molecules themselves has been studied extensively and provide some intriguing insights into the mechanisms that underlie signal transduction by this group of proteins.

Tyrosine phosphorylation takes place at specific locations in the receptor molecule. Once phosphorylated, these sites associate, in highly specific fashion, with a variety of accessory proteins that possess independent signaling capability. These include PLCγ, phosphoinositol (PI) 3′ kinase, GTPase-activating protein (GAP), growth factor receptor–bound protein-2 (GRB2), and the Src family nonreceptor tyrosine kinases. These interactions are fostered by the presence of highly conserved type 2 *src* homology (based on sequence homology to the *src* proto-oncogene) domains (SH2) in each of the accessory molecules. Each individual SH2 domain displays specificity for the contextual amino acids surrounding the phosphotyrosine residues in the receptor molecule. In the PDGF receptor, for example, the SH2 domain of PLCγ associates selectively with Tyr^{977} and Tyr^{989}, whereas that of PI 3′ kinase associates with Tyr^{708} and Tyr^{719}. Thus, diversity of response is controlled by contextual sequences around individual phosphotyrosine residues that determine the types of accessory proteins brought into the signaling complex. These protein–protein interactions may provide a means of directly controlling the signaling molecule in question, perhaps through a change in steric conformation. Alternatively, they may facilitate the sequestration of these accessory proteins in or near the plasma membrane compartment, in close proximity to key substrates (eg, membrane lipids in the case of PLCγ) or other important regulatory proteins.

Some of these associations trigger immediate signaling events, but others (eg, GRB2) may act largely to provide the scaffolding needed to construct a more complex signaling apparatus (Figure 1–10). In the case of GRB2, another accessory protein (son-of-sevenless; SOS) associates with the receptor–GRB2 complex through a type 3 *src* homology (SH3) domain present in the latter. This domain recognizes a sequence of proline-rich amino acids present in the SOS protein. SOS, in turn, facilitates assembly of the Ras–Raf complex, which permits activation of downstream effectors such as mitogen-activated protein kinase (MAPK) kinase (MEK). This latter kinase, which possesses both serine-threonine and tyrosine kinase activity, activates the p42 and p44 MAPKs (also called extracellular signal–regulated kinases; ERKs). ERK acts on a variety of substrates within the cell, including the RSK kinases, which, in turn, phosphorylate the ribosomal S_6 protein and thereby stimulate protein synthesis. These phosphorylation reactions (and their amplification in those instances where the MAPK substrate is a kinase itself) often lead to protean changes in the phenotype of the target cells.
FIGURE 1–10 Growth factor–dependent pathway. Assembly of the components involved in the Ras/Raf/MEK/MAPK and PI-3K/PKB– signaling mechanisms.

The ligand bound growth factor receptors, including the insulin receptor, may also signal through the phosphoinositide 3-OH kinase (PI-3K). SH2 domains of the p85 regulatory subunit of PI-3K associate with the growth factor receptor through specific phosphotyrosine residues (Tyr^{740} and Tyr^{751} in the PDGF receptor) in a manner similar to that described earlier for GRB2 (see Figure 1–10). This leads to activation of the p110 catalytic subunit of PI-3K and increased production of phosphatidylinositol-3,4,5-trisphosphate (PIP_3) and phosphatidylinositol-3,4-bisphosphate ($PI[3,4]P_2$). These latter molecules sequester protein kinase B (also known as Akt) at the cell membrane through association with the plekstrin homology domains in the amino terminal of the kinase molecule. This in turn leads to phosphorylation of PKB at two separate sites (Thr^{308} in the active kinase domain and Ser^{473} in the carboxyl terminal tail) by PIP_3-dependent kinases (PDK1 and PDK2). These phosphorylations result in activation of PKB. In the case of insulin-sensitive target cells, downstream targets of activated PKB (eg, following insulin stimulation) include 6-phosphofructo-2-kinase (increased activity), glycogen synthase kinase-3 (GSK3) (decreased activity), the insulin-responsive glucose transporter GLUT 4 (translocation and increased activity), and p70 S6 kinase (increased activity). This leads to increased glycolysis, increased glycogen synthesis, increased glucose transport, and increased protein synthesis, respectively. This leads to increased glycolysis, increased glycogen synthesis, increased glucose transport, and increased protein synthesis, respectively. There is also a growing body of evidence suggesting that PKB may protect cells from programmed cell death through phosphorylation of key proteins in the apoptotic pathway.

It has been reported that GPCRs may also activate the Raf-MEK-ERK cascade, although in this case the signal traffics through a nonreceptor protein tyrosine kinase (NRPTK such as Src and Fyn) rather than the traditional growth factor receptor–linked tyrosine kinases. The details of the mechanism are incompletely understood, but it appears to require the participation of β-arrestin (discussed earlier) as an adaptor molecule linking the G protein receptor to the NRPTK. Interestingly, this implies that β-arrestin, which normally terminates coupling between the receptor and G protein, can actually promote coupling between the desensitized receptor and downstream effectors traditionally associated with growth factor–dependent activation.

CYTOKINE RECEPTORS

These include the receptors for a variety of cytokines, such as erythropoietin, colony-stimulating factor, GH, and prolactin. These cell membrane receptors have a single internal hydrophobic stretch of amino acids, suggesting that they span the membrane once (see Figure 1–4). They can be composed of monomers or heterodimers of different molecules.

Growth Hormone and Prolactin Receptors

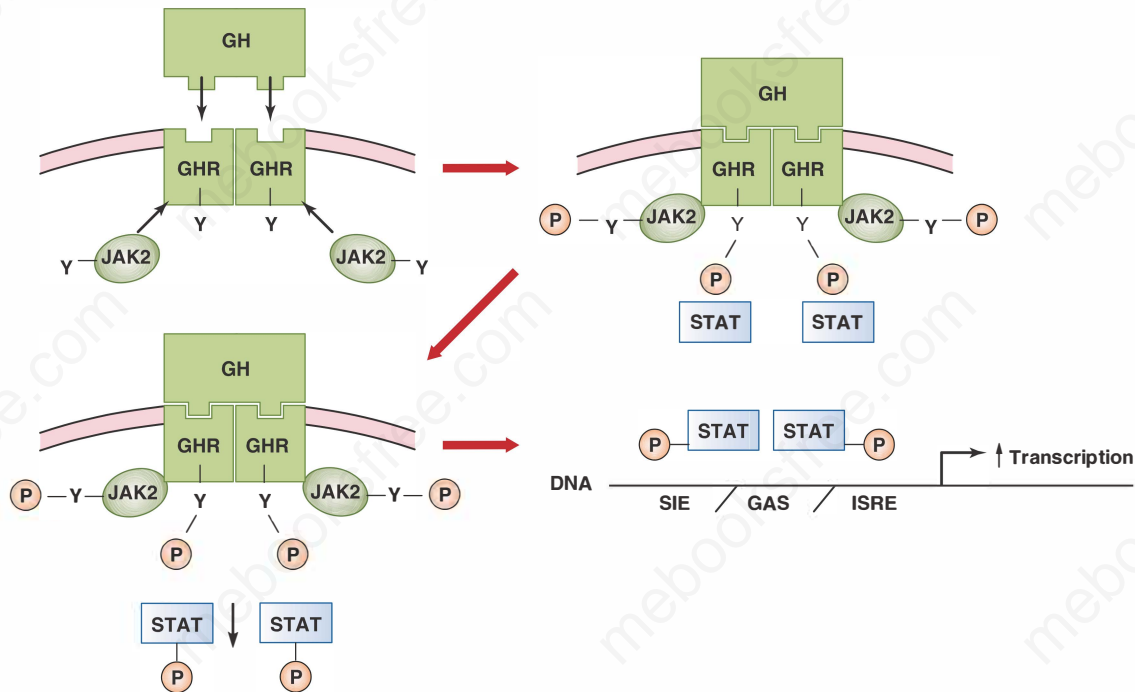
Receptors for GH and prolactin are prototypical cytokine receptors (Figure 1–11). Interestingly, alternative splicing of the GH receptor gene primary transcript results in a foreshortened "receptor" that lacks the membrane anchor and carboxyl terminal domain of the protein. This "receptor" is secreted and serves to bind GH in the extracellular space (eg, circulating plasma). Unlike


FIGURE 1–11 Signaling by the growth hormone receptor (GHR). Different portions of a single growth hormone molecule associate with homologous regions of two independent GHR molecules. This is believed to lead to the recruitment of JAK2, which phosphorylates the GHR, providing a docking site for STAT. The latter is phosphorylated, dissociates from the liganded receptor complex, and migrates to the nucleus, where it associates with binding elements of target genes and regulates transcription.

the growth factor receptors described earlier, GH receptors lack a tyrosine kinase domain. Different domains of a single GH molecule associate with homologous regions of two independent GH receptors, promoting dimerization of the receptors and subsequent association with and activation of Janus kinase (JAK) 2. Janus kinase 2 (JAK2) undergoes autophosphorylation and concurrently tyrosine phosphorylates the GH receptors. The latter provides a docking site for the signal transducer and activator of transcription (STAT) factors; STAT 5a and 5b appear to be particularly relevant to GH and prolactin action. The STATs are phosphorylated, dissociate from the GH receptor, migrate to the nucleus, and bind to specific STAT-binding DNA regulatory elements (SIE/ISRE/GAS) responsible for transcriptional control of GH target genes such as IGF-1. There are a number of different STAT family members, and there is specificity of certain cytokine receptors for certain STAT family members. This helps direct the specificity of signaling by each type of receptor. STAT signaling is also regulated by a family of inhibitors referred to as suppressor of cytokine signaling (SOCS) proteins. SOCS proteins bind to JAK and STAT proteins and target them for degradation. SOCS proteins are induced after cytokine/hormone binding and help to autoregulate signaling in this pathway.

TGF-β Receptors

These receptors bind a variety of ligands that include the cytokine transforming growth factor beta (TGF-β), the hormones inhibin, activin, anti-müllerian hormone (AMH), and the

bone morphogenetic protein (BMP) family. Diseases associated with mutations in the TGF-β receptor pathways can be very dramatic. For example, activating mutations in the type 1 activin A receptor ACVR1 result in severe heterotopic ossification in a disorder known as fibrodysplasia ossificans progressiva (FOP). The ligands for these receptors are typically homo- or heterodimers of subunits that have a highly conserved, cysteine-dependent structure. TGF-β family receptors bind to ligands through a heterodimeric receptor consisting of two transmembrane subunits known as type I and type II receptors (Figure 1–12). There are a number of different type I and type II receptor subunits in this family and type I/type II pairs can form between several different family members. Both type I and type II receptors have an intracellular serine/threonine kinase domain. The type II receptor is constitutively phosphorylated and active, while the type I receptor is not. The ligands in this family initially bind the type II receptor. The type I receptor is then recruited to the complex where the type II receptor kinase phosphorylates and activates the type I receptor, which then further propagates the signal. Downstream in the signaling pathway are a group of phosphorylation targets called the Smad proteins. These proteins, upon phosphorylation, can migrate to the nucleus to activate and/or repress transcription of target genes.

Modulators of TGF-β signaling also play critical roles in human disease. Members of the differential screening-selected gene in neuroblastoma (DAN) family were originally identified as BMP inhibitors and comprise a diverse group of antagonists.
FIGURE 1–12 Signaling by the TGF-β receptors. TGF-β ligand first docks with the type II receptor which has an intracellular serine/threonine kinase domain that is constitutively active. After ligand binding, the type I receptor is then recruited to the complex and the type II receptor can phosphorylate the intracellular serine/threonine kinase domain of the type I receptor. This then propagates the signal downstream leading to the phosphorylation and activation of Smad proteins which can migrate to the nucleus and activate or repress gene transcription.

One DAN protein, sclerostin (SOST), is of particular interest because of its key role in regulating osteoblast anabolic function through the LRP5/6 and Frizzled receptors that bind Wnt. Patients with loss of function mutations in SOST show dramatically increased bone mass and sclerosteosis or van Buchem disease. Antibodies that inhibit sclerostin activity show great promise as bone anabolic agents for treating conditions associated with bone loss.

TNF-Receptors

The tumor necrosis factor (TNF) family of receptors is a large group of cytokine receptors that bind to both soluble and cell-membrane-associated ligands. One important member of this family is the receptor activator of nuclear factor kappa B (RANK) which plays a critical function in the regulation of bone physiology (see Chapter 8). These receptors consist of a trimeric complex of three single transmembrane receptors that bind to ligand. The cytoplasmic tail of many TNF-receptors (including RANK) interacts with a family of adapter molecules called TNF receptor–associated factors (TRAFs) that further activate a number of downstream pathways, the most of important of which is the activation of nuclear factor kappa B (NF-κB) (Figure 1–13). Activation of NF-κB is a central event in many if not all inflammatory responses and leads to the induction of many molecules including those involved in apoptotic, cytokine, and chemokine pathways. TNF-receptor signaling leads to the activation of NF-κB through phosphorylation of the heterotrimeric I-κB kinase (IKK) complex, which then phosphorylates the inhibitor of NF-κB (I-κB). I-κB complexes with NF-κB in the cytosol and keeps it inactive; however, when I-κB is phosphorylated it dissociates from the complex and undergoes degradation through the ubiquitin-dependent

proteasome pathway. NF-κB then translocates to the nucleus where it regulates gene transcription.

WNT/Beta Catenin

Signaling through the Wnt/β-catenin complex is critical for embryonic development and cellular homeostasis. The β-catenin
FIGURE 1–13 TNF receptor signaling. TNF binds to a trimolecular cell surface receptor which transmits a downstream signal that leads to the phosphorylation and activation of the I-κB kinase (IKK). IKK phosphorylates the inhibitor of NF-κB (I-κB) which is then tagged for degradation through a ubiquitin-dependent proteosomal pathway. This allows NF-κB to migrate to the nucleus where it can carry out activation or repression of gene transcription.

proteins are found in two main complexes: as a cadherin cellular adhesion protein-bound form in adherens junctions (Figure 1–14A), and in a complex with APC, Axin, and GSK3 as part of the Wnt signaling pathway (Figure 1–14B).

At the cell membrane, β-catenins serve to promote cell-cell adhesions by linking cadherins to actin filaments (see Figure 1–14A). Mutations in β-catenins appear to play a critical role in the progression towards cancer by regulating the degradation of the Wnt/β-catenin complex or by changing cellular adhesion properties. These mutations are found in colorectal, breast, ovarian, and endometrial cancers.

Beta-catenin can also be regulated by secreted Wnt proteins, providing a key link between extracellular Wnt signaling and activation of genetic developmental programs (see Figure 1–14B). In the Wnt signaling pathway, levels of β-catenins are primarily controlled by ubiquitination and proteosomal degradation. This is triggered through phosphorylation by glycogen synthase kinase 3 alpha and beta (GSK3α and β) and casein kinase I (CKI). This process is amplified by the scaffolding proteins Disheveled and Axin. These components assemble to create a large complex that marks β-catenin molecules for subsequent destruction by proteasomes.

Recently, the activation of the Wnt/β-catenin pathway in osteocytes has been identified as a critical regulator of anabolic bone activity, while activation of the same pathway in osteoblasts may be responsible for decreased bone resorption. As described previously, mutations in the Wnt receptor LRP5/6 can also change osteoblast anabolic function, contributing to high bone mass (activating mutations in LRP5) and diseases such as osteoporosis-pseudoglioma syndrome (loss of function mutations in LRP5). These features make the Wnt/β-catenin pathway particularly intriguing as a therapeutic target for a wide spectrum of disorders.
FIGURE 1–14 Beta-catenin signaling. β-catenin proteins are found in two main signaling complexes: as a cadherin cellular adhesion protein-bound form in adherens junctions **(A)** that promotes cell-cell adhesion and as part of the Wnt signaling pathway in a complex associated with APC, Axin, and GSK3 **(B)**. When the pathway is inactive, the β-catenin complex forms and CKI adds the 4th phosphate, thus activating ubiquitination and subsequent proteasome degradation of β-catenin. Activation of the Wnt signaling receptors Frizzled and LRP5/6 allows unphosphorylated β-catenin to enter the nucleus and activate Wnt responsive genes.

GUANYLYL CYCLASE–LINKED RECEPTORS

Activation of guanylyl cyclase–dependent signaling cascades can occur through two independent mechanisms. The first involves activation of the soluble guanylyl cyclase, a heme-containing enzyme that is activated by the gas nitric oxide (NO) generated in the same or neighboring cells. NO is produced by the heme-containing enzyme nitric oxide synthase. NO synthase exists as three different isozymes in selected body tissues. Constitutive forms of NO synthase (NOS) are produced in endothelial (NOS-3) and neuronal (NOS-1) cells. The endothelial enzyme possesses binding sites for FAD and FMN as well as calcium and appears to require calcium for optimal activity. Endothelial NOS activity is regulated by myristoylation and palmitoylation, which anchor the enzyme in the membrane compartment, and by phosphorylation. Agents such as bradykinin and acetylcholine, which interact with receptors on the surface of endothelial cells and increase intracellular calcium levels, trigger an increase in constitutive NO synthase activity with consequent generation of NO and activation of soluble guanylyl cyclase activity in neighboring vascular smooth muscle cells (Figure 1–15). Thus, in this instance, the cGMP-dependent vasodilatory activity of acetylcholine requires sequential waves of signaling activity in two different cell types to realize the ultimate physiologic effect.

The inducible (i) form of NO synthase (NOS-2) is found predominantly in inflammatory cells of the immune system, although it has also been reported to be present in smooth muscle cells of the vascular wall. Unlike the endothelial form of NO synthase, expression of iNO synthase is low in the basal state. Treatment of cells with a variety of cytokines triggers an increase in new iNO synthase synthesis (hence, the inducible component of iNO synthase activity), probably through activation of specific *cis* elements in the iNO synthase promoter. Thus, hormones, cytokines, or growth factors with the capacity for induction of iNO synthase activity may direct at least a portion of their signaling activity through a cGMP-dependent pathway.

A third mechanism for increasing cGMP levels within target cells involves the activation of particulate guanylyl cyclases (Figure 1–16). From an endocrine standpoint, this involves predominantly the natriuretic peptide receptors (NPR). NPR-A is a single-transmembrane-domain receptor (about 130 kDa) with a large extracellular domain that provides ligand recognition and binding. This is followed by a hydrophobic transmembrane domain and a large intracellular domain that harbors the signaling function. The amino terminal portion of this intracellular region contains an ATP-binding kinase homology domain (KHD) that is involved in regulating cyclase activity, whereas the carboxyl terminal domain contains the catalytic core of the particulate guanylyl cyclase. It is believed that association of ligand with the
FIGURE 1–15 Signaling through the endothelial (e) and inducible (i) nitric oxide synthases (NOS) in the vascular wall. Activation of eNOS in the endothelial cell or iNOS in the vascular smooth muscle cell leads to an increase in NO and stimulation of soluble guanylyl cyclase (GC) activity. Subsequent elevations in cGMP activate cGMP-dependent protein kinase (PKG) and promote vasorelaxation.
FIGURE 1–16 Signaling by particulate guanylyl cyclase. Ligand (ANP or BNP for the type A natriuretic peptide receptor or CNP for the type B receptor) associates with the extracellular domain of the receptor. This effects a change in the receptor that reduces affinity for ligand and alters conformation of the KHD which, in turn, reverses tonic inhibition of particulate guanylyl cyclase activity at the carboxy terminal portion of the receptor. Rac and PAK-1 are thought to activate the receptor through a more direct interaction with the guanylyl cyclase domain. Increased cyclase activity increases cellular cGMP levels which increase protein kinase G (PKG) activity through a mechanism similar to that described for cAMP (see Figure 1–6), regulates phosphodiesterase (PDE) activity, and alters the ion transport properties of the target cell.

extracellular domain leads to a conformational change in the receptor that arrests the tonic inhibitory control of the kinase-like domain and permits activation of guanylyl cyclase activity. Recent studies suggest that the small GTPase Rac can directly activate the catalytic domain through its effector kinase PAK (p21-activated kinase). NPR-B, the product of a separate gene, has a similar topology and a relatively high level of sequence homology to the NPR-A gene product; however, while NPR-A responds predominantly to the cardiac atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), NPR-B is activated by the C-type NP (CNP), a peptide found in the central nervous system, endothelium, and reproductive tissues but not in the heart. Thus, segregated expression of the ligand and its cognate receptor convey a high level of response specificity to these two systems despite the fact that they share a common final effector mechanism. Noteworthy, both NPR-A and NPR-B require a high degree of phosphorylation in the KHD to retain sensitivity to agonist. Dephosphorylation, perhaps through agonist-triggered exposure of the phosphoserine residues to regulatory phosphatase activity in the target cell, results in receptor desensitization. In humans,

homozygous mutation of the *NPR-B* genes results in acromesomelic dysplasia Maroteaux type (AMDM), a rare form of autosomal recessive, short-limbed dwarfism.

NUCLEAR ACTION OF PEPTIDE HORMONES

Although the initial targets of peptide hormone receptor signaling appear to be confined to the cytoplasm, it is clear that these receptors can also have profound effects on nuclear transcriptional activity. They accomplish this through the same mechanisms they use to regulate enzymatic activity in the cytoplasmic compartment (eg, through activation of kinases and phosphatases) via second-messengers that transmit information into the nucleus. In this case, however, the ultimate targets are transcription factors that govern the expression of target genes. Examples include hormonal activation of c-Jun and c-Fos nuclear transcription factors that make up the heterodimeric AP-1 complex. This complex has been shown to alter the expression of a wide variety of eukaryotic genes through association with a specific recognition element, termed the phorbol ester (TPA) response element (TRE), present within the DNA sequence of their respective promoters. Other growth factor receptors that use the MAPK-dependent signaling mechanism appear to target the serum response factor (SRF) and its associated ternary complex proteins. Post-translational modification of these transcription factors is believed to amplify the signal that traffics from this complex, when associated with the cognate serum response element (SRE), to the core transcriptional apparatus. The cAMP-dependent activation of protein kinase A results in the phosphorylation of a nuclear protein CREB (cAMP response element–binding protein) at Ser^{119}, an event that results in enhanced transcriptional activity of closely positioned promoters. The latter requires the participation of an intermediate CREB-binding protein (CBP). CBP is a co-activator molecule that functionally tethers CREB to proteins of the core transcriptional machinery. Interestingly, CBP may also play a similar role in nuclear receptor (NR) signaling (see Nuclear Receptors). Several recent studies have provided evidence suggesting that a number of peptide hormones and growth factors may bind to high-affinity receptors in the cell nucleus. The role these receptors play—if any—in contributing to the signaling profile of these peptides remains undefined.

NUCLEAR RECEPTORS

The NRs, which include those for the glucocorticoids, mineralocorticoids, androgens, progesterone, estrogens, thyroid hormone, and vitamin D, differ from the receptors of the surface membrane described earlier in that they are soluble receptors with a proclivity for using transcriptional regulation as a means of promoting their biologic effects. Thus, although some receptors are compartmentalized in the cytoplasm (eg, glucocorticoid receptor), whereas others are confined to the nucleus (eg, thyroid hormone receptor), they all operate within the nuclear chromatin to initiate the

signaling cascade. These receptors can be grouped into two major subtypes based on shared structural and functional properties. The first, the steroid receptor family, includes the prototypical glucocorticoid receptor (GR) and the receptors for mineralocorticoids (MR), androgens (AR), and progesterone (PR). The second, the thyroid receptor family, includes the thyroid hormone receptor (TR) and the receptors for estrogen (ER), retinoic acid (RAR and RXR), and vitamin D (VDR) as well as the peroxisome proliferator–activated receptor (PPAR). There are also so-called orphan receptors that bear structural homology to members of the extended NR family. For many of these, the "ligand" is unknown, and their functional roles in the regulation of gene expression have yet to be determined. Others have been linked to specific ligands. For example, PPARs bind to fatty acids, FXR with isoprenoids and bile acids, LXR with oxysterols, PXR with steroid metabolites, CAR with xenobiotics, and BXR with folic acid derivatives. In total, there are more than 70 nuclear receptors and orphan receptors in humans.

STEROID RECEPTOR FAMILY

Steroid receptors (ie, GR, MR, AR, and PR), under basal conditions, exist as cytoplasmic, multimeric complexes that include the heat shock proteins (HSPs) 90, 70, and 56 and immunophilins of the FK506 family (FKBP51 and FKBP52). ER, although demonstrating similar association with HSP, is largely confined to the nuclear compartment. Association of the steroid ligand with the receptor results in dissociation of the HSP. This in turn exposes a nuclear translocation signal previously buried in the receptor structure (near DNA binding and hinge regions, see later) and initiates transport of the receptor to the nucleus, where it associates with the hormone response element (Figure 1–17).

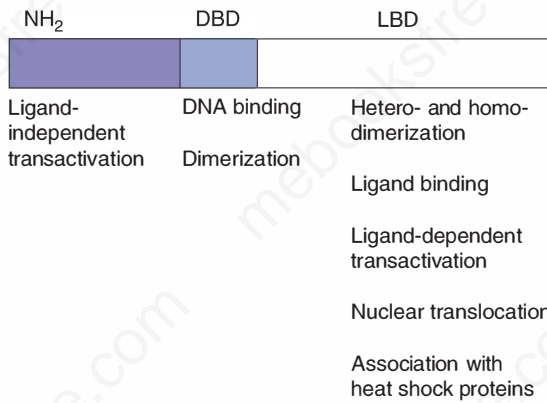
Each of the family members has been cloned and sequenced, and crystallographic structures have been obtained for many of them. Consequently, we know a great deal about their structure
FIGURE 1–17 Signaling through the steroid receptor complex. Similar mechanisms are employed by members of the *TR* gene family, though most of the latter are concentrated in the nuclear compartment and are not associated with the HSP complex prior to binding ligand (^meG, methyl guanosine).


FIGURE 1–18 Structural schematic of a representative steroid receptor molecule. Separate designations are given to the amino terminal (NH$_2$), DNA-binding (DBD), and ligand-binding (LBD) domains. Functional activity associated with each of these individual domains, as determined by mutagenesis studies, is indicated under each individual domain.

and function (Figure 1–18). Each has an extended amino terminal domain of varying length and limited sequence homology to other family members. In at least some receptors, this region, which has been termed AF-1, is believed to participate in the transactivation function through which the individual receptors promote increased gene transcription. Significant variability in the length of the amino terminal regions of the different receptors suggests potential differences in their respective mechanisms for transcriptional regulation. In fact, different AF-1 domains display differential affinity for interaction with coactivator proteins (see later). The amino terminal is followed by a basic region that has a high degree of

sequence homology in both the steroid and thyroid receptor gene families. This basic region encodes two zinc finger motifs (Figure 1–19) that have been shown to establish contacts in the major groove of the cognate DNA recognition element (see the discussion later). Based on crystallographic data collected for the DNA-binding region of the GR, we know that the amino acid sequence lying between the first and second fingers (ie, recognition helix) is responsible for establishing specific contacts with the DNA. The second finger provides the stabilizing contacts that increase the affinity of the receptor for DNA. The DNA-binding region also harbors amino acid residues that contribute to the dimerization of monomers contiguously arrayed on the DNA recognition element. Following the basic region is the carboxyl terminal domain of the protein. This domain is responsible for binding of the relevant ligand, receptor dimerization or heterodimerization, and association with the HSPs. It also contributes to the ligand-dependent transactivation function (incorporated in a subdomain termed AF-2) that drives transcriptional activity. Interestingly, in selected cases, nonligands have been shown to be capable of activating steroid receptors. Dopamine activates the progesterone receptor and increases PR-dependent transcriptional activity, probably through a phosphorylation event, which elicits a conformational change similar to that produced by the association of the receptor with progesterone.

The DNA-binding regions of these receptors contact DNA through a canonical HRE, which is described in Table 1–3. Interestingly, each receptor in the individual subfamily binds to the same recognition element with high affinity. Thus, specificity of hormone action must be established either by contextual DNA sequence lying outside the recognition element or by other, nonreceptor DNA-protein interactions positioned in close proximity
FIGURE 1–19 Schema of the two zinc fingers, together with coordinated zinc ion, which make up the DNA-binding domain of the GR (amino acids are numbered relative to the full-length receptor). Shaded regions denote two alpha helical structures which are oriented perpendicularly to one another in the receptor molecule. The first of these, the recognition helix, makes contact with bases in the major groove of the DNA. Red arrows identify amino acids which contact specific bases in the glucocorticoid response element (GRE). Black arrows identify amino acids that confer specificity for the GRE; selective substitutions at these positions can shift receptor specificity to other response elements. Dots identify amino acids making specific contacts with the phosphate backbone of DNA. (Reproduced with permission from Luisi BF, Xu WX, Otwinowski Z, et al. Crystallographic analysis of the interaction of the glucocorticoid receptor with DNA. *Nature*. 1991 Aug 8;352(6335):497-505.)

TABLE 1–3 DNA recognition elements for major classes of nuclear hormone receptors.[a]

Element	Recognition Sequence	Receptor
HRE	AGAACANNNTGTTCT	Glucocorticoid Mineralocorticoid Progesterone Androgen
ERE	AGGTCANNNTGACCT	Estrogen
TRE	AGGTCA(N)$_n$AGGTCA	Vitamin D Thyroid hormone Retinoic acids PPAR ligands

[a]Elements represent consensus sequences selected to emphasize the modular nature of the half-sites and their capacity for palindrome generation. Sequences read in the 5′ to 3′ direction. N denotes a spacer nucleoside (either A, G, C, or T). Half-sites are identified by the overlying arrows. The TRE is arrayed as a direct repeat but may also exist as a palindrome or an inverted palindrome. A variable number of spacer nucleotides are positioned between the two direct repeats, depending on the type of hormone receptor. Three, four, and five nucleosides (ie, n = 3, 4, or 5) are preferred for binding of the VDR, TR, or RAR, respectively.

to the element. Interestingly, the GR, as well as some other NRs (eg, ER), are capable of binding to DNA sequence lacking the classic HRE. Originally described in the mouse proliferin gene promoter, these composite elements associate with heterologous complexes containing GR, as well as with components of the AP-1 transcription factor complex (ie, c-Jun and c-Fos). They display unique regulatory activity at the level of contiguously positioned promoters. One such composite element, for example, directs very specific transcriptional effects depending on whether the GR or the MR is included in the complex.

Several steroids, particularly the glucocorticoids and estrogens, have been reported to have independent effects on the stability of target gene transcripts. At this point, it is unclear what role the hormone receptors play in this process and whether transcript stabilization is tied mechanistically to the enhancement of transcriptional activity.

THYROID RECEPTOR FAMILY

The thyroid receptor family includes the TR, RAR, RXR, ER, PPAR, and VDR. They share a high degree of homology to the proto-oncogene c-erbA and high affinity for a common DNA recognition site (see Table 1–3). With the exception of the ER, they do not associate with the HSPs, and they are constitutively bound to chromatin in the cell nucleus. Specificity of binding for each of the individual receptors is, once again, probably conferred by a contextual sequence surrounding this element, the orientation of the elements (eg, direct repeats or inverted repeats or palindromes), the polarity (ie, 5′ in contrast to 3′ position on two successive repeats), and the number and nature of the spacing nucleotides separating the repeats.

The ER binds to its RE as a homodimer, whereas the VDR, RAR, RXR, and TR prefer binding as heterodimers. The nature of the heterodimeric partners has provided some intriguing insights into

the biology of these receptors. The most prevalent TR-associated partners appear to be the RXRs. These latter receptors, which as homodimers form high-affinity associations with 9-cis-retinoic acid, also form heterodimeric complexes in the unliganded state with VDR and RAR. In the individual cases in which it has been examined, heterodimerization with RXR amplifies both the DNA binding and the functional activity of these other receptors. Thus, the ability to form such heterodimeric complexes may add significantly to the flexibility and potency of these hormone receptor systems in regulating gene expression. Interestingly, the positioning (5′ vs 3′) of the participant proteins on the RE is important in determining the functional outcome of the association. In most of those situations linked to transcriptional activation, RXR seems to prefer the upstream (5′) position in the dimeric complex. Thus, diversity of response is engendered by the selection of recognition elements (eg, monomeric vs dimeric vs oligomeric sites) and by the choice and positioning of the dimeric partner (eg, homodimer vs heterodimer) where applicable.

The crystallographic structures of the LBDs of several members of the TR family have been described. These include the dimeric unliganded RXRα, monomeric liganded RARγ, monomeric liganded TRα, dimeric agonist (ie, estradiol)—and antagonist (ie, raloxifene)—liganded ERα, liganded VDR, and liganded PPARγ. A composite LBD displays a common folding pattern with 12 alpha helices (numbered by convention H1-H12) and a conserved beta turn. Some variability exists in that there is no H2 in RARγ and a short H2′ helix is present in PPARγ, but the overall structural configuration is preserved. The dimeric interface is formed through interaction of amino acids located in helices 7 to 10, with the strongest influence exerted by H10. These interactions appear to be important for both homodimeric as well as heterodimeric interactions. Binding of ligand has been shown to occur through what has been termed a "mousetrap" mechanism. In the unliganded state, H12, which contains the carboxyl terminal activation domain AF-2, is displaced away from the ligand-binding pocket (Figure 1–20). Association of agonist ligand (eg, estradiol in the case of the ER) with the hydrophobic core of the receptor leads to a repositioning of H12 over the ligand-binding cavity, where it stabilizes receptor–ligand interactions and closes the "mousetrap." Binding of an antagonist ligand such as raloxifene, which because of its structure engenders steric hindrance in the ligand-binding pocket, prevents closure of H12 into the normal agonist position. Instead, H12 folds into an alternative location between H4 and H3, a conformation that suppresses the activation function of the receptor (discussed later). Crystal structure of a full-length nuclear receptor pair (in this case PPAR gamma and RXR alpha) shows that the PPAR gamma protein dominates its heterodimeric partner, dictating the overall structure of the complex.

The mechanistic underpinnings of transcriptional regulation by the NRs have been partially elucidated (Figure 1–21). In the unliganded or antagonist-bound state, the receptor dimers are preferentially associated with a macromolecular complex containing the repressor proteins N-CoR or SMRT, a transcriptional corepressor Sin3, and a histone deacetylase RPD3. N-CoR and SMRT each use two independent receptor interaction domains

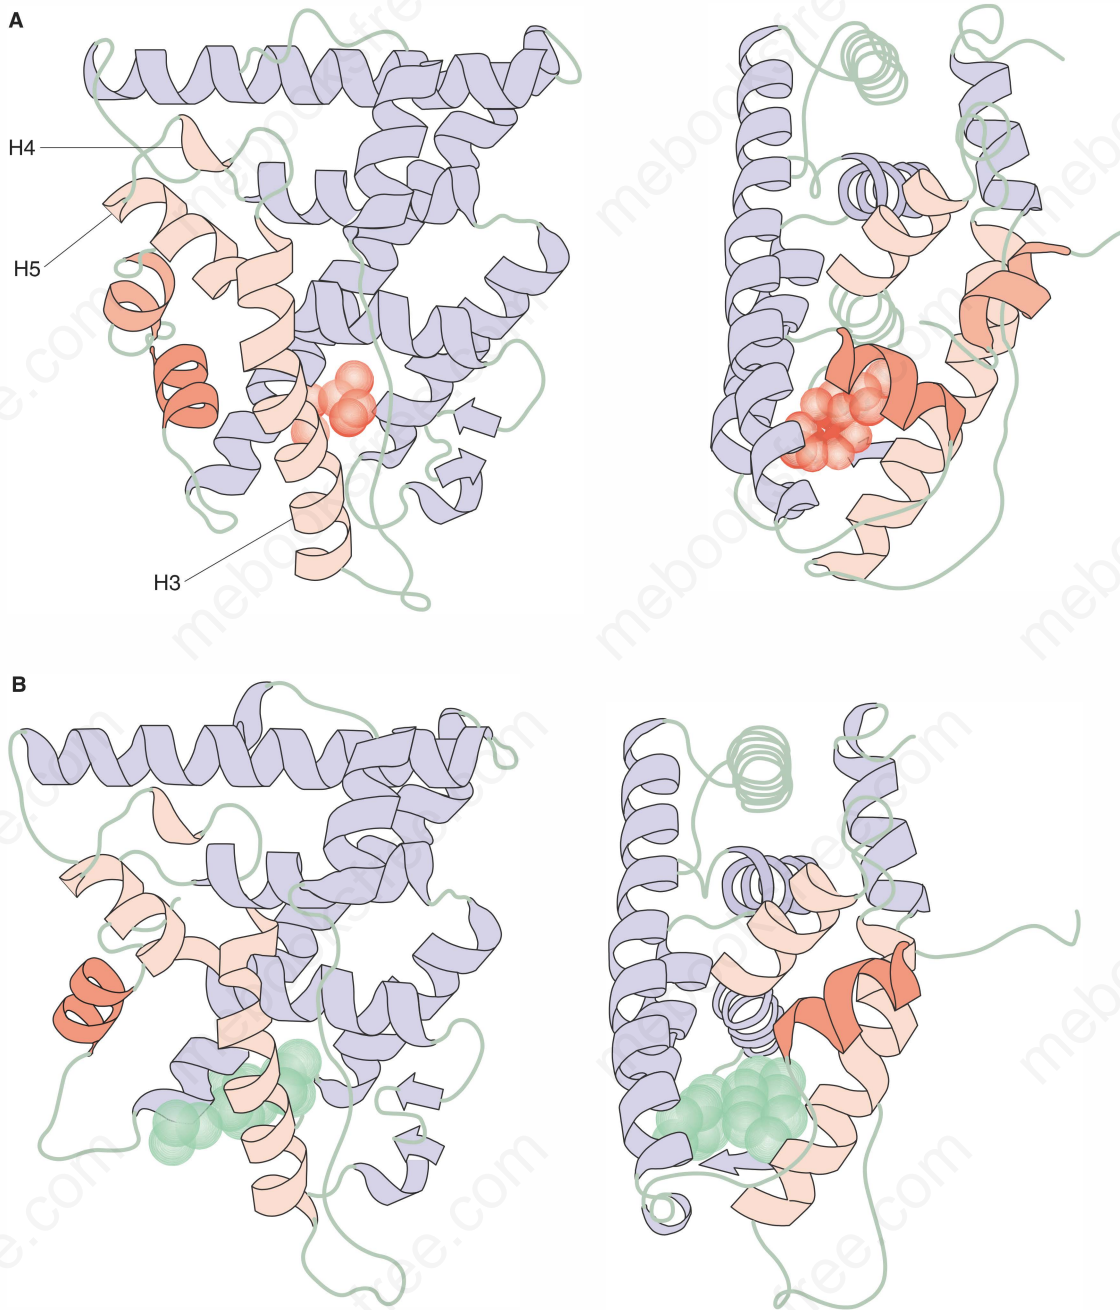

FIGURE 1–20   Three-dimensional structures for the agonist- and antagonist-occupied ERα LBD. **(A)** Orthogonal views of the agonist diethylstilbestrol-ERα LBD-NR Box II peptide complex. Coactivator peptide and LBD are presented as ribbon diagrams. Peptide is colored medium orange, helix (H) 12 (ERα residues 538-546) is colored dark orange. Helices 3, 4, and 5 are colored light pink. Diethylstilbestrol is depicted in red in a space-filling format. **(B)** Orthogonal views of the antagonist 4-hydroxytamoxifen-ERα LBD complex. Color scheme is the same as in panel A. 4-Hydroxytamoxifen is shown in green in a space-filling format. Note that NR Box II is absent in this structure. **(C)** Schematic representation of the mechanism underlying agonist-dependent activation of nuclear hormone receptor (see next page.) In the presence of agonist, helix 12 (the terminal helix in the LBD) folds across the ligand-binding pocket, stabilizing ligand–receptor interaction and promoting a conformation conducive for coactivator association. In the presence of antagonist, steric hindrance precludes folding of helix 12 across the ligand-binding pocket. Instead, it positions itself in the region typically occupied by the coactivator, thereby blocking the activation function of the receptor. (Reproduced with permission from Shiau AK, Barstad D, Loria PM, et al. The structural basis of estrogen receptor/coactivator recognition and the antagonism of this interaction by tamoxifen. *Cell*. 1998 Dec 23;95(7):927-937.)

C
FIGURE 1–20 (*Continued*)

(IDs) to associate with the NRs (one repressor; two receptors). Each ID contains an amino acid sequence (L/IXXI/VI, where I = isoleucine, L = leucine, V = valine, X = any amino acid), which interacts with helices 4, 5, and 6 of the NR LBD. Histone acetylation is typically associated with activation of gene transcription (presumably reflecting decompaction of chromatin surrounding the transcriptional unit), so the presence of histone deacetylase activity in the complex is thought to promote a transcriptionally quiescent state. Addition of ligand leads to a change in receptor conformation that no longer favors interaction with the corepressor (a shift in position of helix 12 in the LBD prevents corepressor interaction and promotes coactivator assembly into the complex) and promotes both ATP-dependent chromatin remodeling and assembly of an activator complex containing p160 coactivator proteins (eg, SRC-1, GRIP-1, or P/CIP) and, secondarily, the CREB-binding protein (CBP) and the histone acetylase P/CAF. The net accrual of histone acetylase activity (CBP and P/CIP as well as P/CAF possess acetylase activity) leads to acetylation of chromatin proteins (eg, histones) as well as components of the core transcriptional machinery, resulting in chromatin decompaction and a net increase in transcriptional activity. Interaction of the NRs with the coactivators in this complex takes place through LXXLL motifs (where L = leucine and X = any amino acid) present in the coactivator proteins. Each coactivator may have several of these motifs, which preferentially associate with different NRs, other transcription factors, or other coactivators. This allows for a degree of selectivity in terms of which regulatory proteins are incorporated in the complex. Notably, a recent structural analysis showed that a 13-amino-acid peptide, containing an LXXLL motif from the GRIP-1 protein, interacts with TRβ through a hydrophobic cleft generated by helices 3, 4, and 12 (including AF-2) in the receptor protein. This is the same cleft that is occupied by helix 12, which harbors an LXXLL motif, in the raloxifene-bound ERα. This suggests that the antagonist in the latter instance acquires its activation-blocking properties by repositioning helix 12 in a manner that leads to displacement of the coactivator protein from this groove (see discussion earlier). SRC also interacts with the AF-1 domain, suggesting a potential mechanism for maximizing synergistic activity between AF-1 and AF-2 domains in the receptors. The importance of SRC1 in thyroid hormone action is underscored by the finding that SRC1 knockout mice display significant thyroid hormone resistance in peripheral tissues.

CBP is thought to function as a pivotal component of the NR regulatory complex. While the p160 class of coactivators interact directly with the NRs (primary coactivator), CBP associates primarily with the p160 coactivators, thereby establishing an indirect link to the receptors (secondary coactivator). CBP also has the ability to establish weaker, primary associations with the receptor proteins. As noted earlier, CBP functions as a central integrator of transcriptional regulatory signals from multiple pathways, including the cAMP-dependent activation of the transcription factor CREB. Recent evidence suggests that an additional level of regulatory control may be involved in selectively amplifying NR-dependent transcriptional activity. An enzyme called coactivator-associated arginine methyltransferase 1 (CARM1) associates with CBP and methylates the protein. This results in a reduction in CREB-dependent gene activation and, secondarily, an increase in NR-dependent gene transcription. This switching mechanism effectively refocuses the transcriptional machinery on expression of NR-dependent gene expression. CARM1 also interacts with all three members of the SRC family. It binds to the AD2 domain at the carboxy terminus of the p160 coactivators (by contrast, CBP associates with the AD1 domain located in the midregion of the molecule). CARM1 in this context promotes methylation of the p160 coactivator and dissociation of the CARM1-SRC complex from NR-associated DNA, effectively clearing the promoter of the transcriptional regulatory complex.

Another family of coactivator complexes has also been identified as playing an important role in NR signaling. The human TR-associated protein (TRAP) and vitamin D receptor–interacting protein (DRIP) complexes are the best characterized to date. These complexes, which contain in the neighborhood of 25 individual proteins, are thought to serve as a functional bridge between the liganded NR bound to DNA and the general transcription factors (GTFs) (eg, TBP, TFIIB, RNA polymerase II, and TAFs) involved in formation of the preinitiation complex, a function previously assigned to the Mediator complex in yeast. The TRAP220 subunit appears to establish the relevant contacts, through LXXLL motifs, with the NRs in promoting this assembly. Their role vis-à-vis the p160 coactivators alluded to earlier remains undefined; however, it has been suggested that they succeed the p160 coactivator complex in binding with liganded NRs positioned on target gene promoters, establish the requisite structural and functional connections with the core transcriptional machinery, and initiate mRNA synthesis. It has also been suggested that acetylation of one of the key NR-binding motifs (LXXLL) on the SRC coactivator by CBP leads to dissociation of SRC from the nuclear receptors, thereby allowing access for assembly of the TRAP/DRIP complex (see Figure 1–21).

Nuclear receptors can be post-translationally modified through acetylation, ubiquitination, and phosphorylation. Modifications are common in the amino terminal AF-1 domain where they can affect the affinity for selected coactivator proteins and, thereby, modulate receptor activity. Phosphorylation, which is the most extensively studied of these modifications, can affect virtually all nuclear receptors. Phosphorylation by kinases associated with the general transcriptional machinery (eg, cyclin-dependent kinase 7) or major intracellular signaling pathways (eg, Akt) may serve to recruit coactivators into the complex, thereby facilitating transcriptional regulation. Coactivator molecules or other factors recruited into the multisubunit transcription complexes may possess kinase, ubiquitin ligase, ATPase, methyltransferase, or acetylase activity which can target either nuclear receptors or other coregulators. Thus, in addition to their ability to provide the scaffolding for complex assembly, they also possess the enzymatic capacity to fine tune the transcriptional activity of the complex. Coactivators themselves can undergo post-translational modification. Phosphorylation of the SRC coactivators, for example, can increase coactivator affinity for selected nuclear steroid receptors (eg, AR, PR, and ER), as well the p300 and CBP proteins, thereby increasing the stability of the activation complex. In addition to

their effects on transcription, coactivators have been suggested to be involved in transcript elongation, RNA splicing, and mRNA transport.

Recent studies have shown that a significant portion of ER DNA-binding sites in MCF7 cells (a breast cancer cell line) are topographically linked to, or in some cases directly overlap with, those for the forkhead box transcription factor A1 (FOX A1). FOX A1 has been referred to as a pioneer factor that aids in positioning ER (or AR) at specific sites on DNA. FOX A1 is recruited to specific epigenetic markers in chromatin; in the case of MCF7 cells this is a lysine 4 methylation on histone 3. This, in turn, directs ER binding to nearby regions on the DNA. Similar findings have been reported with the AR, albeit with different epigenetic chromatin markers.

Although the GR is encoded by a single gene, there are several translation start sites and the primary gene transcript can be alternatively spliced to generate a number of variants, some of which (eg, GR β) may exert dominant negative activity when paired with the predominant receptor (eg, GR α). GR beta is abundantly expressed in neutrophils and epithelial cells where it may be responsible for suppressing glucocorticoid activity. TR is encoded by two genes (α and β). TR α1 and TR β1 appear to be the dominant forms of TR in the body. Although considerable overlap exists in their tissue distribution, TR α1 is enriched in skeletal muscle, brown fat, and the central nervous system, and TR β1 is found in the liver, kidney, and central nervous system. They are believed to signal most of the developmental and thermogenic effects of thyroid hormone in the whole animal. TR β2, a splice variant of the TR β gene, is found in the rodent pituitary gland, where it may subserve a specific regulatory function (eg, control of TSH secretion). TR α2, an alternatively spliced product of the TR α gene, lacks the HBD at the carboxyl terminal of the molecule and thus is not a true thyroid hormone receptor. Under certain experimental conditions, TR α2 can block the activity of other members of the TR family, but its physiologic role, if one exists, remains undefined.

Similar heterogeneity exists in the retinoid receptor family. There are three isoforms for both the RXR and RAR. Collectively, these receptors are thought to play an important role in morphogenesis, but the function of the individual isoforms remains only partially understood. There are two ER isoforms. ERα appears to signal the bulk of traditional estrogenic activity. ERβ is found in a variety of different tissues and possesses antiproliferative activity that may serve to dampen the effects of liganded ER.

NONGENOMIC EFFECTS OF THE STEROID HORMONES

Although steroids exert most of their biologic activity through direct genomic effects, there are several lines of evidence suggesting that this does not provide a complete picture of steroid hormone action. There are several examples that, for kinetic or experimental reasons, do not fit the classic paradigm associated with a transcriptional regulatory mechanism. Included within

this group are the rapid suppression of ACTH secretion following steroid administration, the modulation of oocyte maturation and neuronal excitability by progesterone, the stimulation of endothelial nitric oxide synthase (through interaction of ERα with the p85 subunit of PI-3K) by estrogen, the inhibition of type II deiodinase and stimulation of mitochondrial oxygen consumption by thyroid hormone, and regulation of calcium channel function by 1,25-$(OH)_2$ vitamin D. Recent studies have demonstrated the presence of conventional sex steroid, vitamin D, and thyroid hormone receptors on membranes of target cells. Attachment of these to the membrane requires palmitoylation of internal cysteine residues that leads to association of the membrane-bound receptor with caveolae. These caveolae traffic the receptors to signaling complexes or "rafts" within the membrane. The PR displays a novel ability to interact with the SH3 domains of the Src family tyrosine kinases, thereby accessing the Ras/Raf/MEK-1/ERK signaling pathway (discussed earlier). Although we still do not completely understand the mechanisms underlying these nongenomic effects, their potential importance in mediating steroid or thyroid hormone action may, in selected instances, approach that of their more conventional genomic counterparts.

Neurosteroids represent another class of nontraditional hormonal agonists with unique biologic activity. Some of these are native steroids (eg, progesterone), whereas others are conjugated derivatives or metabolites of the native steroids (eg, dihydroprogesterone). These agonists have been identified in the central nervous system and in some instances shown to have potent biologic activity. It is believed that they operate through interaction with the receptor for γ-aminobutyric acid, a molecule that increases neuronal membrane conductance to chloride ion. This has the net effect of hyperpolarizing the cellular membrane and suppressing neuronal excitability. Interactions that promote receptor activity would be predicted to produce sedative-hypnotic effects in the whole animal, whereas inhibitory interactions would be expected to lead to a state of central nervous system excitation.

STEROID AND THYROID HORMONE RECEPTOR RESISTANCE SYNDROMES

Heritable defects in these receptors have been linked to the pathophysiology of a number of hormone-resistance syndromes. These syndromes are characterized by a clinical phenotype suggesting hormone deficiency, by elevated levels of the circulating hormone ligand, and increased (or inappropriately detectable) levels of the relevant trophic regulatory hormone (eg, ACTH, TSH, FSH, or LH). Point mutations in the zinc fingers of the DNA-binding domain as well the LBD of the VDR lead to a form of vitamin D–dependent rickets (type II) characterized by typical rachitic bone lesions, secondary hyperparathyroidism, and alopecia. It is inherited as an autosomal recessive disorder. Molecular defects scattered along the full length of the AR (>400 to date), although concentrated in the LBD, have been linked to syndromes

characterized by varying degrees of androgen resistance ranging from infertility to full-blown testicular feminization syndrome. Clinical severity, in this case, is thought to be related to the severity of the functional impairment that the mutation imposes on the receptor. Because the AR is located on the X chromosome, these disorders are inherited in an X-linked fashion.

Defects in the GR are less common, perhaps reflecting the life-threatening nature of derangements in this system. However, mutations have been identified that impact negatively on receptor function. Clinical presentations in these cases have been dominated by signs and symptoms referable to glucocorticoid deficiency (eg, fatigue, asthenia) and adrenal androgen (eg, hirsutism and sexual precocity) and mineralocorticoid (eg, low renin hypertension) overproduction. This presumably results from defective steroid-mediated suppression of ACTH secretion and adrenal hyperplasia as the former rises in an attempt to restore glucocorticoid activity at the periphery.

Resistance to thyroid hormone has been linked to a large number of mutations scattered along the full length of the β form of the receptor, although, once again, there is a concentration of mutations in the LBD, particularly along the rim of the coactivator-binding pocket. The clinical presentation of thyroid hormone resistance resulting from a defective TR beta extends from the more typical mild attention-deficit syndromes to full-blown hypothyroidism with impaired growth. Different target tissues harboring the mutant receptors display variable sensitivity to thyroid hormone, with some tissues (eg, pituitary) displaying profound resistance and others (eg, heart) responding in a fashion suggesting hyperstimulation with thyroid hormone (ie, thyrotoxicosis). The latter effects (eg, tachycardia) may reflect the predominance of the normal α isoform, as opposed to defective β TR isoform, in the target tissue (eg, heart). Mutation of the alpha form of TR was described recently. It leads to significant growth and developmental retardation, skeletal dysplasia, and severe constipation. These syndromes are rather unique in that they are inherited as autosomal dominant disorders, presumably reflecting the ability of the mutated receptors to interfere with receptors produced from the normal allele, either by binding to the RE with higher affinity than the wild-type receptors and precluding access of the latter to target genes or by forming inactive heterodimers with the wild-type receptor proteins (ie, dominant negative mutant receptor). Mutations in the thyroid receptor can also result in agonist-dependent association with transcriptional repressors (eg, N-CoR and SMRT) resulting in a reduction in transcriptional activity. A number of patients with thyroid hormone resistance have been described that lack mutations in the TR. In two cases, the defect has been assigned to defects in the transport and intracellular metabolism of thyroid hormone.

Defects in the ER are rare, perhaps reflecting the critical role estrogens play in regulating lipoprotein metabolism. However, one male patient who harbors a mutation within the LBD of the ER has been described. His clinical presentation was characterized by infertility as well as osteopenia, suggesting important roles for estrogens in the maintenance of spermatogenesis as well as bone growth even in male subjects.

A novel mutation in the PPARγ receptor leads to a phenotype that resembles that of patients with the metabolic syndrome (ie, severe insulin resistance, diabetes mellitus, and hypertension). A syndrome of mineralocorticoid resistance, or pseudohypoaldosteronism, has been described in a number of independent kindreds. Pseudohypoaldosteronism type I is characterized by neonatal renal salt wasting, dehydration, hypotension, hyperkalemia, and hyperchloremic metabolic acidosis despite the presence of elevated aldosterone levels. Heterozygous mutations in the MR are responsible for a milder form of the disease which is inherited in an autosomal dominant pattern with abnormalities largely confined to the kidney. A more severe form of the disease with generalized systemic involvement is inherited in an autosomal recessive pattern and appears to be due to loss-of-function mutations in genes encoding subunits of the amiloride-sensitive epithelial sodium channel. Of equivalent interest is the recent identification of an activating mineralocorticoid receptor mutation (Ser_{810}-to-Leu_{810}). This mutation results in severe early-onset hypertension that is markedly exacerbated by pregnancy. The mutation leads to constitutive activation of the MR and alters the specificity of ligand binding such that traditional MR antagonists, like progesterone, function as partial agonists. This latter property presumably accounts for the dramatic increase in blood pressure during pregnancy. Genetic deficiency of coactivators have also been linked to human disease. Expression levels of PPARγ coactivator alpha (PGC-1α) have been linked to metabolic disorders like diabetes mellitus and obesity. Mutation of the CBP gene leads to the Rubenstein-Taybi syndrome characterized by defective development and impaired long-term memory formation.

Epidemiologic analysis of a large population reported that about 1 of 30 (3.2%) people in the United States are currently affected by autoimmune diseases. Graves disease, type 1 diabetes, pernicious anemia, rheumatoid arthritis, Hashimoto thyroiditis, and vitiligo are the most prevalent such conditions, accounting for 93% of affected individuals. A more global approach at calculating prevalence led to a corrected estimate between 7.6% and 9.4% of the world's population as affected by autoimmune diseases (2.5 in 30 people worldwide).

These autoimmune diseases have traditionally been looked upon as forming a spectrum. At one end are found organ-specific diseases with organ-specific targets. Hashimoto thyroiditis is an example in which a specific lesion affects the thyroid (lymphocytic infiltration, destruction of follicular cells) and autoantibodies are produced with absolute specificity for thyroid proteins. At the other end of the spectrum are the systemic autoimmune diseases, broadly belonging to the class of rheumatologic disorders. Systemic lupus erythematosus is an example of a disease characterized by widespread pathologic changes and a collection of autoantibodies to DNA and other nuclear constituents of all cells. Many organ-specific autoimmune diseases are autoimmune endocrinopathies. Furthermore, most endocrine glands are subject to autoimmune attack including the adrenals (autoimmune Addison disease), gonads (autoimmune oophoritis), pancreas (type 1 diabetes), pituitary (autoimmune hypophysitis), and thyroid (autoimmune thyroid disease) (Table 2–1).

TABLE 2–1 Some autoimmune endocrinopathies, antigens, and autoantibodies.

Disease	Gland	Autoantigen	Autoantibody
Autoimmune (lymphocytic) hypophysitis Granulomatous hypophysitis	Pituitary	Pituitary cytosolic protein	Anti-pituitary
Graves disease	Thyroid	TSH-R, TPO	TSI, TBII, anti-TPO
Hashimoto thyroiditis	Thyroid	TPO, Tg	Anti-TPO, anti-Tg
Autoimmune (idiopathic) hypoparathyroidism	Parathyroid	CaSR, NALP5, IFN alpha, IFN omega, other cytokine antibodies	Antiparathyroid
Type 1 diabetes mellitus	Pancreas (β cells)	GAD65, IA-2, pre-pro-insulin	Anti-GAD, anti-IA-2 (ICA), anti-insulin
Type B insulin resistance with acanthosis nigricans (rare)	Adipocytes, muscle cells	Insulin receptor	Insulin receptor blocking
Autoimmune Addison disease (autoimmune adrenal failure)	Adrenal	21-Hydroxylase 17α-Hydroxylase P450scc	Anti-21-hydroxylase (ACA) Anti-17α-hydroxylase and anti-P450scc (SCA)
Autoimmune oophoritis (premature ovarian failure)	Ovaries	Not yet identified unequivocally, 17α-hydroxylase P450scc	Also SCA in association with adrenal insufficiency
Autoimmune orchitis/Male infertility (some forms)	Testes	Sperm	Anti-sperm

By far the most common autoimmune endocrine diseases are those involving the thyroid and the endocrine pancreas. When the target is the thyroid gland and the clinical manifestation is hypothyroidism (Hashimoto thyroiditis), the prevalence is about 1% to 2%. When the manifestation is hyperthyroidism (Graves disease), the prevalence is about 0.4%. Both thyroid autoimmune disorders affect women preferentially. When the targets of the autoimmune response are the β cells of the pancreas, the clinical presentation is type 1 diabetes. The prevalence of type 1 diabetes is close to that of Graves disease (0.2%-0.5%); however, it has no gender predilection.

Basic immunologic concepts as they apply to clinical autoimmune endocrine diseases as sole entities and as polyendocrine failure syndromes are reviewed in this chapter.

BASIC IMMUNE COMPONENTS AND MECHANISMS

The immune system is constantly confronted with a variety of molecules and recognizes them as either self or foreign. The adaptive immune system has evolved to recognize virtually any foreign molecule, either in existence or yet to come. The repertoire of immune recognition molecules randomly formed by gene rearrangements is not limited by the genetic information encoded in the genome (Figure 2–1). As a result, an enormously wide array of immune recognition molecules is acquired by the human immune system. By way of illustration, the theoretical diversity of T-cell receptors (T-cell recognition molecules) by random rearrangements reaches 10^{15}. This mechanism of rearrangement also applies to B-cell recognition molecules (ie, immunoglobulins). The random mechanism of gene rearrangement, however, produces immune recognition molecules that react with self components. Potentially dangerous immune cells carrying self-reactive recognition molecules are eliminated (negatively selected) during development of T lymphocytes in the thymus and of B

lymphocytes in the bone marrow. It appears that only immune cells which react with foreign antigen strongly and with self antigen very weakly are positively selected and comprise the peripheral immune cell repertoire. This selection mechanism of immune cells is termed "central tolerance." Self-reactive immune cells that skip central tolerance and reach the periphery are managed by other control mechanisms against autoimmunity and are either eliminated, rendered unresponsive, or suppressed ("peripheral tolerance"). Failures in these mechanisms of immunologic regulation, as proposed by Mackay and Burnet in 1964, are central features of the concept of autoimmunity.

IMMUNE RECOGNITION AND RESPONSE

T and B lymphocytes are the fundamental and predominant immune cells. T lymphocyte precursors (pre-T cells) originate in the bone marrow and migrate to the thymus, where they undergo maturation and differentiation. At early stages, they express several T-cell surface molecules but still have genomic (not rearranged) configuration of their T-cell receptors (TCRs). These pre-T cells, destined to become T cells with TCR α/β chains (T α/β cells), pass through a critical phase during which self-reactive T cells are deleted by negative selection (see T-Cell Tolerance, later in this chapter). Few pre-T cells will express other types of chains on their TCR (T γ/δ cells). T α/β cells differentiate into either mature CD4 or CD8 cells. These now mature lymphocytes migrate to T-cell areas of peripheral lymphoid organs and exert their function as helper (T_H) or cytotoxic (T_C) cells when activated.

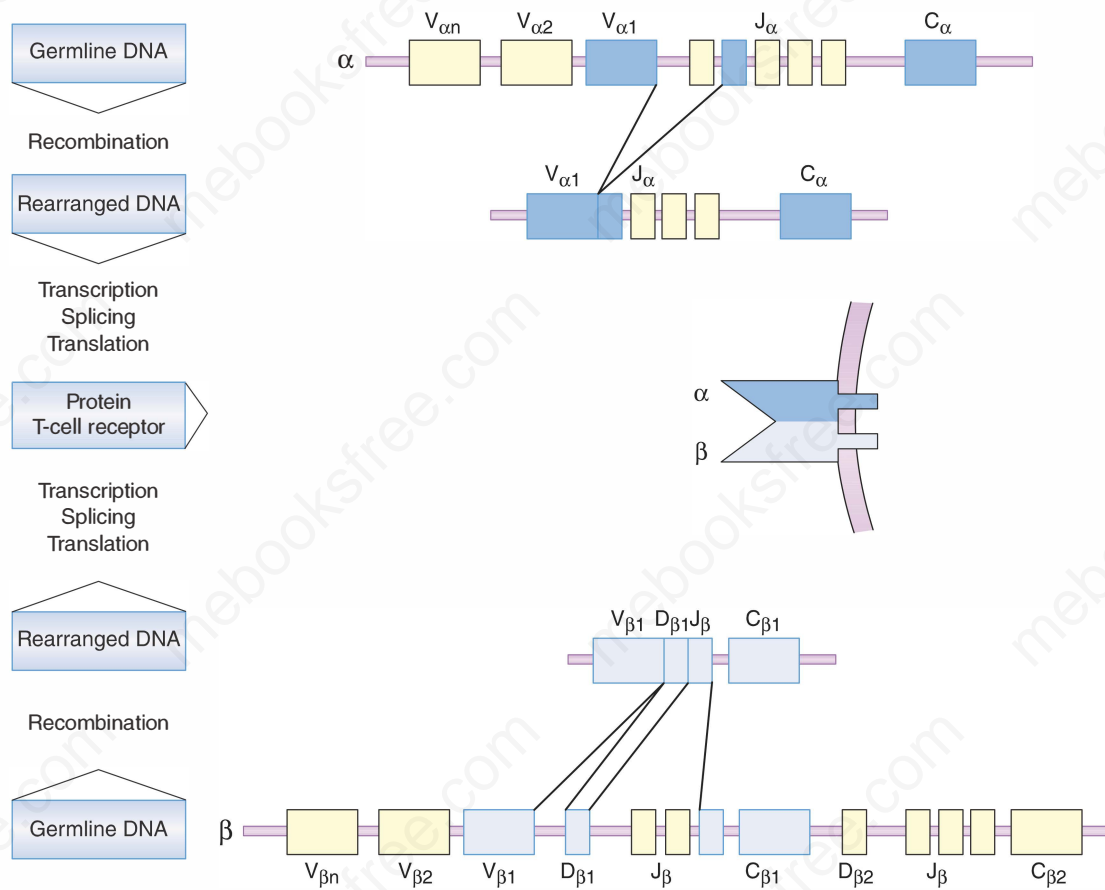
B lymphocytes mature and differentiate in the bone marrow and then migrate to the B-cell areas of lymphoid organs. Influenced by factors derived from T_H cells previously activated by professional antigen-presenting cells (APCs) such as macrophages, some B cells differentiate to become immunoglobulin M (IgM)-producing cells (plasma cells). Most of the other activated B cells that do not


FIGURE 2-1 Rearrangement of the T-cell receptor (TCR) α and β genes to form a functionally diverse receptor. During T-cell development, the TCR α and β gene segments rearrange by somatic recombination so that one of the V_{α} segments pairs with a single J_{α} segment, and a V_{β} segment pairs with a single D_{β} and J_{β} segment. The C (constant) segments are brought together with the rearranged segments by transcription and splicing to generate the functional mRNA that will be translated into the α and β protein chains that compose the TCR.

differentiate into plasma cells revert to the resting state to become memory B cells. When memory B cells are further activated, two events occur: isotype switching (immunoglobulin class switching) and hypermutation of the immunoglobulin-variable region to further increase diversity and specificity (affinity maturation).

Activation of B cells requires recognition of the antigen as a whole, while T cells require recognition of antigenic peptides bound to major histocompatibility complex (MHC) molecules on the surfaces of professional APCs. Therefore, T-cell recognition is said to be MHC restricted.

The human MHC (human leukocyte antigen; HLA) consists of a linked set of genes encoding major glycoproteins involved in antigen presentation (Figure 2–2). The complex locates to the short arm of chromosome 6 and divides into three separate
FIGURE 2-2 Gene organization of the human major histocompatibility complex or human leukocyte antigen (HLA) complex. Regions encoding the three classes of MHC proteins are on top. APTP denotes a cluster of genes within the class II region, encoding genes related to antigen processing, transport, and presentation. Class III region encodes genes unrelated to class I or class II not involved in antigen presentation (TNF-α and β, complement factors C2, C4, B, and 21-hydroxylase and others).

regions: class I, class II, and class III genes. The class I "classic" region encodes HLA-A, HLA-B, and HLA-C loci; the nonclassic or class I-related region encodes HLA-E, HLA-F, and HLA-G loci and other immunity-related genes such as CD1. The class II region (HLA-D) encodes HLA-DP, HLA-DQ, and HLA-DR loci and other genes related to antigen processing, transport, and presentation, such as transporter associated with antigen processing (TAP). The class III region encodes genes for tumor necrosis factors α and β (TNF-α and TNF-β); complement factors C2, C4, and B; and the steroidogenic enzyme 21-hydroxylase. MHC class I (classic) molecules are found on all somatic cells, whereas MHC class I nonclassic antigens are expressed only on some (eg, HLA-F on fetal liver, HLA-G on placental tissues). CD1 molecules are expressed on Langerhans cells, dendritic cells, macrophages, and B cells (all professional APCs). MHC class II molecules are exclusively expressed on these professional APCs. However, virtually all cells except mature erythrocytes can express MHC class II molecules under particular conditions (eg, stimulation with interferon-γ [IFN-γ]). As a general rule, MHC class I molecules present peptides derived from endogenous antigens that have access to cytosolic cell compartments (eg, virus) to CD8 T_C cells. On the other hand, MHC class II molecules present peptides derived from antigens internalized by endocytosis into vesicular compartments (eg, bacteria) to CD4 T_H cells. MHC class II molecules also bind peptides derived from many membrane-bound self antigens.

APCs process and present antigen in order to activate T cells utilizing MHC-peptide presentation (Figure 2–3). T cells require at least two signals to become activated. The interaction of a TCR expressed on antigen-specific T cells and the antigenic peptide–MHC complex expressed on APCs provides the first signal. The second signal is delivered primarily by the interaction between costimulatory molecules CD80 (B7.1) and CD86 (B7.2) on APCs and CD28 on T cells. These two signals induce proliferation of T cells, production of interleukin-2 (IL-2), and expression of the antiapoptotic protein Bcl-xL. T_H cells and T_C cells are effector cells that require both signals in order to become activated. However, T_C cells also need the "help" provided by T_H cells. Until recently, it was thought that T_H and T_C cells needed to interact with the same APC simultaneously and that cytokines (such as IL-2) produced by the T_H cell would then act on the T_C cell to facilitate its response. New studies suggest that the interaction between another costimulatory molecule, CD40 ligand (CD154), present on T cells, and CD40, present on APCs, may provide an alternative explanation. It appears that T_H cell–recognizing antigenic peptides presented by APCs deliver a signal through the CD154–CD40 complex that "licenses" APCs to directly stimulate T_C cells (Figure 2–4). Thus, there is no need for simultaneous interactions of T_H and T_C cells while encountering the APC. CD154–CD40 interaction also enhances expression of CD80 and CD86 as well as secretion of cytokines (IL-1, -6, -8, -10, and -12 and TNF-α).

Yet another molecule on T cells, the CD28 homolog cytotoxic T lymphocyte antigen 4 (CTLA-4 or CD152), functions to suppress T-cell responses (see Figure 2–3). CD152 is expressed at low to undetectable levels on resting T cells. It is upregulated by the
FIGURE 2–3 Antigen recognition by T cells. From top to bottom: **A. Antigen uptake**: Incorporation of antigen (via phagocytosis, pinocytosis, or FcR-mediated endocytosis of immune complex). **B. Antigen presentation**: APCs deliver an antigen-specific signal through the MHC-peptide–TCR interaction on T cells (MHC I coupled to CD8 interacts with T_C cells, MHC II coupled to CD4 interacts with T_H cells). **C. T-cell activation**: The required second signal is provided via CD80/86 (B7.1; B7.2)–CD28 that induces the expression of CD154 (CD40 L) first and CD152 (CTLA-4) later on. Binding of CD154 on T cells with CD40 on APCs enhances expression of CD80/86. The APC–CD80/86 increased expression and consequent binding of CD28 on T cells perpetuates the activation and proliferation of these effector cells (downstream events). **D. T-cell inactivation**: CD152 (expressed 48-72 hours after T-cell activation) will preferentially bind to CD80/86 on APCs because of its higher affinity, displacing CD28 and in turn suppressing T-cell activity.
FIGURE 2–4 Licensed APCs directly activate T_C cells. According to the traditional model, T_H cells and T_C cells recognize antigen on the same APC. The APC-activated T_H cell produces IL-2, which contributes to the activation of T_C cells while in simultaneous interaction with the same APC. According to the proposed new model **(A)**, APCs are licensed to activate T_C cells by T_H or other stimuli (lipopolysaccharides, IFN-γ, viruses). APCs first interact with T_H cells. The association of CD154 (CD40 L) on the T_H cell and CD40 on the APC allows (or licenses) the latter to activate T_C cells directly **(B)**. Thus, once licensed, APCs are capable of activating cytotoxic T cells without the need of simultaneous interaction with T_H cells.

ligation of CD28 on T cells with CD80/86 on APCs, or by IL-2. CD152 and CD28 on T cells share the same counterreceptors, namely, CD80/86 on APCs. However, CD152 has a 20-fold higher affinity than CD28 for their ligands.

The integration of all these interactions may be as follows (see Figure 2–3): After processing antigen, APCs deliver an antigen-specific first signal through the MHC-peptide–TCR interaction on T cells. A second signal is provided by a costimulatory interaction of the CD80/86–CD28 complex that induces the expression of CD154 first and then CD152. Binding of CD154 on T_H cells with CD40 on APCs enhances expression of CD80/86 and licenses APCs for direct activation of T_C cells. Other inflammatory cytokines as well as lipopolysaccharides and viruses may do the same. The increased expression of APC–CD80/86 and consequent binding of CD28 on T cells then perpetuates the activation and proliferation of these effector cells. However, the expression of CD152 48 to 72 hours after T-cell activation leads to the preferential binding of this molecule to CD80/86 on APCs because of its higher affinity for CD80/86. This may displace CD28 from CD80/86 and, in turn, suppress T-cell activity. This sequence of complex events is probably simplistic relative to what nature has to offer. A new B7 family of receptors has been reported: some with positive costimulatory capacity, many with a role in down-regulating immune responses, yet others with dual functions. For some of these pathways, such as B7H3/H4 (expressed in APCs with unknown counterreceptor on T cells), very little is known, but even for those pathways that have been extensively studied—such as the CD80/86:CD28/CTLA-4 (mentioned earlier), B7:ICOS (inducible costimulator), and PD-L1/PD-L2:PD1—new insights are still being generated. The intricacies of controlling T-cell activation are enhanced by the complexity of the costimulatory pathways, such that there are multiple possible receptor–ligand interactions.

Activation and differentiation of B cells often require two signals, too. Naive B cells are triggered by antigen but may also require accessory signals that come from activated T_H cells. Some antigens can directly activate naive B cells without the need for T_H cells (eg, lipopolysaccharides from gram-negative bacteria or polymeric protein structures). The former type of B-cell activation (MHC class II–restricted T cell help) is called thymus dependent (TD). The latter type is called thymus independent (TI). T_H cells also control isotype switching and initiate somatic hypermutation of antibody variable-region genes (see Tolerance, discussed later). Interaction between CD154 on T_H cells and CD40 on B cells and the cytokines produced by T_H cells are essential for isotype switching and formation of germinal centers in peripheral lymphoid organs. The immunoglobulin isotype switching is critical for the generation of functional diversity of a humoral immune response. Somatic hypermutation (point mutations of the variable-region genes of immunoglobulins during the course of an immune response) is necessary for the affinity maturation of antibodies.

Overall, the immune response is a combination of effector mechanisms that function to eliminate pathogenic organisms. These effector mechanisms include, as **innate immunity**, phagocytosis (by macrophages, neutrophils, monocytes, and dendritic cells) and cytotoxicity (by natural killer [NK] cells); and as **adaptive immunity**, antibody-dependent complement-mediated cytotoxicity, antibody-dependent cell-mediated cytotoxicity (ADCC), cytotoxicity by T γ/δ cells that recognize heat shock proteins on target cells, and cytotoxicity by CD8 or CD4 T_C cells. CD8 and CD4 T_C cells are activated by the described recognition of specific antigenic peptides bound to class I (for CD8), class II (for CD4) MHC molecules on the APCs and classically by IL-2 from nearby activated CD4 T_H cells. These cells kill the target by either secreting cytotoxins (perforin, granzyme) or by inducing apoptosis through the Fas–FasL (Fas ligand) interaction (killer cells carrying FasL molecules activate programmed cell death in target cells expressing Fas molecules). FasL or CD95L is a type II transmembrane protein that belongs to the TNF family. The binding of FasL with its receptor induces apoptosis. FasL–Fas receptor interactions play an important role in the regulation of the immune system.

The specificity of the immune response is crucial if self-reactivity is to be avoided. In order to ensure that lymphocyte responses and the downstream effector mechanisms they control are directed exclusively against foreign antigens and not against "self" components, a number of safety-check barriers must be negotiated before autoreactive lymphocytes can differentiate and proliferate.

TOLERANCE

T-Cell Tolerance

T cells developing in the thymus (pre-T cells) are destined to become T α/β cells through rearrangement of the TCR β gene initially, followed by the TCR α gene (Figure 2–5). If unproductive rearrangements of TCR genes occur (nonfunctional TCR α or β proteins), apoptosis of these pre-T cells follows (Figure 2–5A). If functional rearrangements of TCR α and β proteins occur, cells express TCR α/β dimer and CD3 molecules at low levels on the cell surface. TCR-rearranged cells proliferate 100-fold. Positive and negative selection occurs based on the ability of the rearranged TCR α/β to recognize antigenic peptides in association with self-MHC molecules on thymic epithelial and dendritic cells. Negative selection (clonal deletion) appears to take place in the thymus medulla, where pre-T cells bearing TCRs specific for self peptides bound to self-MHC molecules are deleted. At least 97% of developing T cells undergo apoptosis within the thymus (central tolerance). Positively selected pre-T cells increase expression of TCR α/β, express either CD4 or CD8, and become mature T cells. These mature T cells exit the thymus and go to the periphery. CD4 T cells are activated in the periphery in an MHC class II–restricted fashion, while CD8 T cells are activated in an MHC class I–restricted fashion.

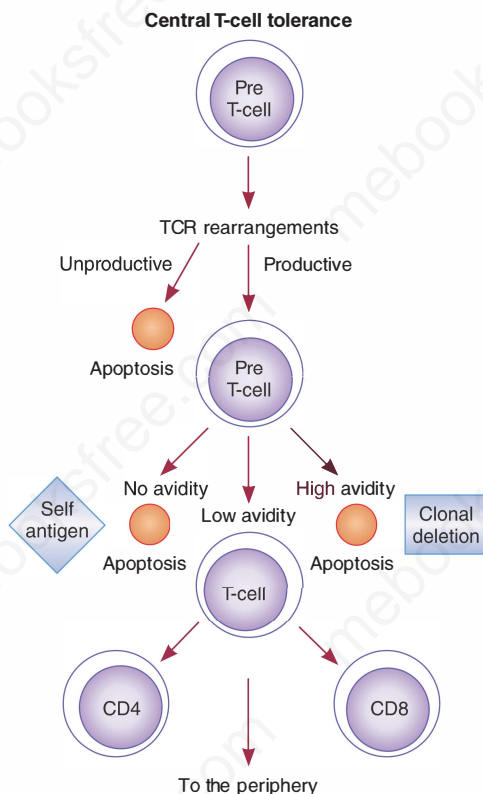
A differential avidity model in which the fate of T cells is determined by the intrinsic affinity of TCRs for their ligands has been advanced to explain the paradox between positive and negative selection. According to this model, T cells with high avidity for MHC-self peptide complexes would be eliminated (negative selection), whereas T cells with low avidity to MHC-self peptide


FIGURE 2–5   A. Central T-cell tolerance: Mechanisms of central tolerance (at the thymus level) are depicted. From top to bottom, pre-T cells first rearrange their TCR. Unproductive (nonfunctional) rearrangements lead to apoptosis, while productive ones engage pre-T cells in self-antigen recognition. Clonal deletion indicates elimination of cells based on their high or no avidity for self antigen (apoptosis). Surviving low-avidity cells reach the periphery as mature CD4 and CD8 cells. **B. Peripheral T-cell tolerance**: May be accomplished through any of the five depicted mechanisms. **1. Clonal deletion**: After encountering self antigen in the context of self-MHC molecules and simultaneous delivery of a second signal (CD80/86–CD28) by APCs (top left), autoreactive T cells become activated. These activated T cells express Fas molecules on their

complexes would be positively selected. If the avidity is close to zero, T cells would not be selected (for lack of effective signal to survive). The biochemical factor or factors that signal survival (low avidity of TCR binding) versus apoptosis (triggered by high avidity interactions) have yet to be found.

Costimulatory interactions between CD28 and CD80/86 and between CD154, CD40, and adhesion molecules, such as lymphocyte function-associated antigen-1 (LFA-1), are also involved in preferential deletion of self-reactive T cells in the medullary region of the thymus. It is known that negative selection is not 100% effective and that some potentially autoreactive T cells do escape to the periphery. Not all self peptides would be presented to pre-T cells during their development in the thymus. Self peptides derived from secluded proteins (ie, intracytoplasmic enzymes) only timely expressed after rigid regulatory control (ie, puberty) in endocrine glands are believed to be a likely source. Therefore, the peripheral immune system must maintain tolerance through complementary control mechanisms.

"Peripheral tolerance" (Figure 2–5B) may be maintained by the induction of unresponsiveness to self antigen (**anergy**) or by the induction of regulatory T cells (T regs), such as suppressor T cells. Peripheral **clonal deletion** (apoptosis) of autoreactive T cells that have escaped from the thymus may play an important role in limiting rapidly expanding responses, but there are many examples where autoreactive T cells persist. Some autoreactive T cells may never encounter the self antigen because it may be sequestered from the immune system (**ignorance**). Lastly, **immune deviation**, whereby noninflammatory T_{H2} responses suppress an autoreactive inflammatory T_{H1} response, inducing peripheral tolerance, deserves further discussion. T_{H1} cells, which regulate cell-mediated responses, secrete IFN-γ and small amounts of IL-4. In contrast, T_{H2} cells, which provide help for antibody production, secrete abundant IL-4 and little IFN-γ. A prevailing concept in human autoimmunity is that T_{H1} responses are believed to dominate. It has been shown in animal models that induction of T_{H2} responses ameliorates T_{H1} responses. Hence, unbalanced T_{H1} immune deviation may lead to a breakage of peripheral tolerance. However, evidence to the contrary exists in some endocrinopathies. (See autoimmune response in the section on Autoimmune Aspects of Thyroid Disease, later in the chapter.)

Clonal deletion and **anergy** occur through apoptosis at the site of activation or after passage through the liver. High antigen dose and chronic stimulation induce peripheral elimination of both CD4 and CD8 T cells. Activated T cells express Fas molecules on their surfaces but are resistant to FasL-mediated apoptosis because of the simultaneous expression of Bcl-xL (apoptosis-resistance molecules), induced by CD28 ligation during activation (see Immune Recognition and Response, earlier in the chapter). Several days after activation, when Bcl-xL has declined, CD4 cells become susceptible to Fas-mediated apoptosis (activation-induced cell death; AICD). A similar mechanism via p75 TNF receptor has been shown for CD8 cells. Therefore, autoreactive T cells might be deleted by apoptosis induced by chronic stimulation with self antigens, present abundantly in the periphery. However, autoreactive T cells specific for very rare self antigens may be difficult to eliminate.

Anergy also results from the lack of a second costimulatory signal. When nonhematopoietic cells stimulated by IFN-γ present antigen in an MHC class II–restricted fashion (as thyrocytes do in AITD), autoreactive T cells may be rendered unresponsive because of the absence of a CD28–CD80/86-mediated signal (nonhematopoietic cells do not express CD80/86 as professional APCs do). However, even if the two signals are provided, anergy may result from the lack of T_H cell-originated cytokines (IL-2, -4, -7, etc). It has also been shown that *in vivo* T-cell anergy may be induced by CD80/86–CD152 interaction (see also Immune Recognition and Response, discussed earlier).

T-cell **active suppression** is considered to be a major regulatory mechanism of peripheral tolerance; however, its mode of action is still under study. As mentioned earlier, nonhematopoietic cells stimulated by IFN-γ present antigen in an MHC class II–restricted fashion to T cells and render them anergic. These nonhematopoietic cells (nonprofessional APCs) may also present to CD4 T-suppressor cells (T_S, also known as CD4 + CD25 + FOXP3 + T regs). Before becoming unresponsive, these cells may induce specific CD8 T suppressor (T_S) cells. In turn, these CD8 T_S cells may regulate (via T-cell-suppressor factors or cytotoxicity) autoreactive T cells (see also Figure 2–5B).

B-Cell Tolerance

Instead of the thymus, the bone marrow provides the setting for central B-cell tolerance. Pre-B cells rearrange their B-cell receptor (BCR or membrane-bound immunoglobulin) early in development. The immunoglobulin heavy (H) chain genes rearrange first, followed by light (L) chain gene rearrangement. Unproductive rearrangements and pairings leading to formation of nonfunctional immunoglobulin drive pre-B cells to apoptosis (Figure 2–6A). Functional rearrangements (functional BCRs) allow immature

surface but are resistant to Fas ligand (FasL)-mediated apoptosis because of the simultaneous expression of Bcl-xL (not shown) induced by CD28 ligation during activation. Several days after activation, when Bcl-xL presence has declined, CD4 cells become susceptible to FasL-mediated apoptosis. Natural killer cells (NK-T) may then accomplish the task of eliminating these autoreactive T cells. **2. Anergy**: Anergy may be induced via CD80/86–CD152 interaction 48 to 72 hours following activation or may result from the lack of a second costimulatory signal from APCs presenting self antigen (nonprofessional APCs). **3. Active suppression**: Active suppression is thought to occur when nonhematopoietic cells (stimulated by IFN-γ) present antigen in an MHC class II–restricted fashion to CD4 T-suppressor cells (T_S, also known as CD4 + CD25 + FOXP3 + T regs). Before becoming unresponsive, these cells may induce specific CD8 T_S cells. In turn, these CD8 T_S cells may suppress antigen-specific autoreactive T cells. **4. Ignorance (top right)**: Some autoreactive T cells may never encounter self antigen because it may be sequestered from the immune system. Although they may persist in the circulation, they never become activated. **5. Immune deviation**: Under specific circumstances, noninflammatory T_{H2} responses could suppress inflammatory (autoreactive) T_{H1} responses (see text).

A

Central B-cell tolerance

B

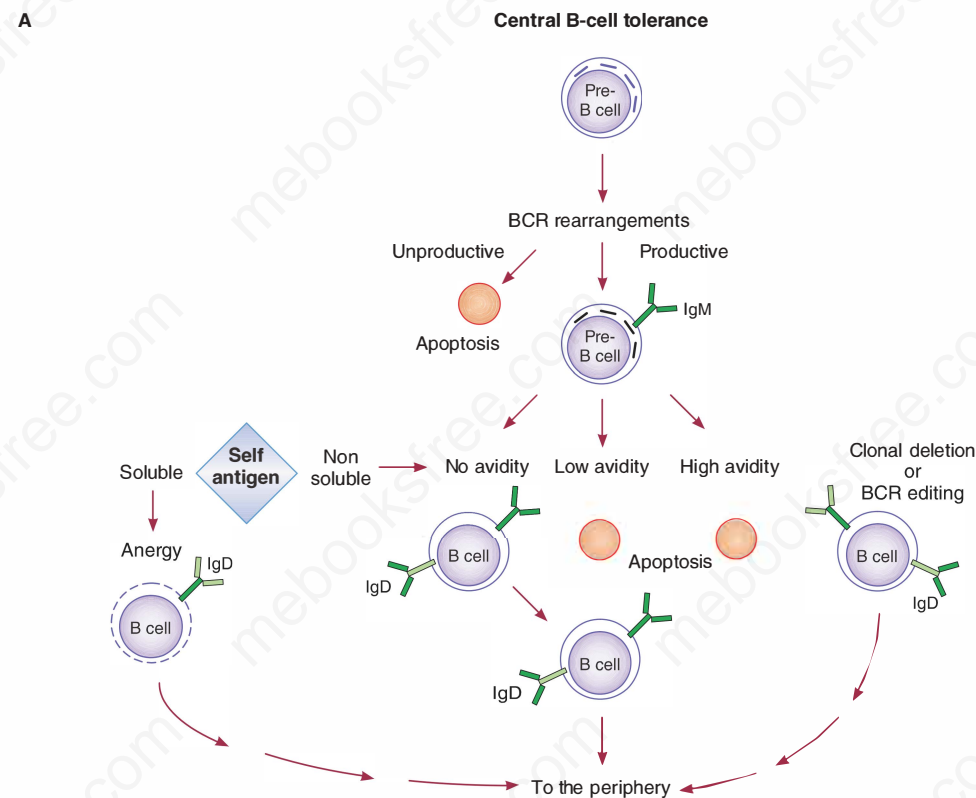
Peripheral B-cell tolerance


FIGURE 2–6   **A. Central B-cell tolerance**: As T cells do in the thymus, B cells rearrange their B-cell receptor (BCR) in the bone marrow. Unproductive rearrangements drive pre-B cells to apoptosis. Functional rearrangements allow expansion and expression of IgM. Next, similar to T-cell clonal deletion, immature B cells that strongly bind self antigens in the bone marrow are eliminated by apoptosis. Some autoreactive immature B cells, instead of becoming apoptotic, however, resume rearrangements of their L-chain genes, attempting to reassemble new allelic

B-cell expansion and expression of IgM and CD21 (a marker of functionality). Only one-third of the precursor cells reach this stage. The random rearrangement of the V, D, and J segments of immunoglobulin genes during this period inevitably generates self-recognizing immunoglobulins. Negative selection of autoreactive B cells occurs at the immature B cell stage on the basis of the avidity of the BCR for self antigens. Similar to the T-cell clonal deletion, immature B cells that strongly bind antigens in the bone marrow are eliminated by apoptosis. Some autoreactive immature B cells, instead of undergoing apoptosis, resume rearrangements of their L-chain genes in an attempt to reassemble new κ or λ genes. This procedure, called **BCR editing**, permanently inactivates the auto-reactive immunoglobulin genes. Soluble antigens, presumably because they generate weaker signals through the BCR of imma-ture B cells, do not cause apoptosis but render cells unresponsive to stimuli (anergy). These anergic B cells migrate to the periphery, where they express IgD. They may be activated under special cir-cumstances, making anergy less than sufficient as a mechanism of enforcing tolerance. Only immature B cells in the bone marrow with no avidity for antigens (membrane-bound or soluble) become mature B cells with the capacity to express both IgM and IgD. As with T cells, 97% of developing B cells undergo apoptosis within the bone marrow. Also, and as with T cells, **central clonal dele-tion**, **anergy**, and **BCR editing** eliminates autoreactive B cells, recognizing bone marrow-derived self antigens.

Peripheral B-cell tolerance (Figure 2–6B) is also crucial for protection against autoimmunity. It appears that in the absence of antigen, mature B cells are actively eliminated in the periphery by activated T cells via Fas–FasL and CD40–CD154 interactions. In the presence of specific antigen but without T-cell help, antigen recognition by BCRs induces apoptosis or anergy of mature B cells. If antigen and specific T-cell help are provided—that is, if antigen bound to the BCR is internalized, processed, and pre-sented in an MHC class II–restricted fashion to a previously acti-vated T_H cell specific for the same antigen—two events occur. One, the B cell becomes an IgM-secreting plasma cell, and—in the presence of the appropriate cytokines and after expression of CD40 (for T_H cell CD154 interaction)—class switching occurs. Two, further somatic hypermutation of the immunoglobulin variable region genes of such mature B cells, which changes affinity of BCRs for antigens, also occurs in germinal centers (see also Immune Recognition and Response, discussed earlier). Mutants with low-affinity receptors undergo apoptosis, while enhanced-affinity BCRs are positively selected. In the presence of CD40 ligation of CD154, antigen-stimulated B cells become memory B cells (see Figure 2–6B).

The ability of mature B cells to capture very low quantities of antigen via high-affinity BCRs allows them to amplify their anti-gen-presenting capacity to more than 1000 times that of other professional APCs. This particular property may become critical in the development of chronic organ-specific autoimmune dis-eases in which the source of antigen is limited. Thus, autoreactive B cells that happen to escape the control mechanisms described could amplify and perpetuate autoimmune responses in patients with failing endocrine organs when tissue destruction has left only minute amounts of residual antigen.

AUTOIMMUNITY IS MULTIFACTORIAL

Although the breakage of self-tolerance seems to be a central pathogenic step in the development of autoimmune diseases, autoimmunity is a multifactorial event. Specifically, defects in apoptosis-related molecules (Fas–FasL) of thymic dendritic cells have been shown to impair central clonal deletion. Also, in the periphery, similar defects (Fas–FasL, CD152) on T cell-APC mol-ecules may prevent apoptosis of autoreactive T cells. However, it is difficult to consider these general defects as causative of organ-specific disorders. Furthermore, clonal ignorance of T cells cannot be maintained if antigens sequestered from the immune system are released in blood or if cryptic epitopes of antigens that have never been recognized by the immune system are presented to T cells for recognition (after tissue destruction, for example). Defects of active suppression (T regs dysfunction, CTLA-4 downregulation), immune deviation (T_{H1}/T_{H2} imbalance), and defects in B-cell tolerance may all be involved in the pathogenesis of autoimmune diseases. How and why loss of immune self-tolerance occurs is not completely understood. Both genetic and environmental factors appear to be necessary.

GENETIC FACTORS IN AUTOIMMUNITY

Epidemiologic studies demonstrate that susceptibility to most autoimmune diseases has a significant genetic component. In type 1 diabetes, for example, there is a clear association between race and susceptibility to disease—the incidence is approximately

---

κ or λ genes (BCR editing). Soluble self antigens presumably generate weaker signals through the BCR of immature B cells; they do not cause apoptosis but make cells unresponsive to stimuli (anergy). These anergic B cells migrate to the periphery, expressing IgD, and may be activated under special circumstances. Only immature B cells with no avidity for antigens become mature B cells, expressing both IgM and IgD. These are the predominant cells that make it to the periphery. **B. Peripheral B-cell tolerance**: In the "absence" of antigen (top right), mature B cells are actively eliminated by activated T cells via Fas–FasL and CD40–CD154 interactions. In the "presence" of specific self antigen but "without T-cell help," antigen recognition by BCRs induces apoptosis or anergy on mature B cells. If self antigen and specific autoreactive T-cell help are pro-vided, two events develop (center): (1) The B cell becomes an IgM-secreting plasma cell (top left), and, in the presence of the appropriate cyto-kines after expression of CD40 (for T_H cell CD154 interaction), class switching occurs (bottom left). (2) Further somatic hypermutation of the Ig-variable region genes, which changes affinity of BCRs, occurs. Mutants with low-affinity receptors undergo apoptosis, while improved-affinity BCRs are positively selected. In the presence of CD40 ligation of CD154, antigen-stimulated B cells become memory B cells. These two events are the same as in foreign antigen recognition.

40 times higher in Finland than in Japan. Family studies also demonstrate a strong underlying genetic component. The lifetime risk of developing type 1 diabetes in the United States general population is 0.4%, whereas in relatives of diabetics the risk is substantially higher (4% for parents, 5%-7% for siblings, 20% for HLA-identical siblings, 25%-40% for monozygotic twins).

The inheritance pattern of autoimmune disorders is complex. These disorders are polygenic, arising from several independently segregating genes. The most consistent genetic marker for autoimmune diseases to date is the MHC genotype. Considering again genetic susceptibility to type 1 diabetes, up to 95% of Caucasians developing diabetes express the HLA alleles DR3 or DR4—compared to about 40% of normal individuals. Individuals heterozygous for both DR3 and DR4 have the highest risk. It has been shown that the DQ rather than DR genotype is a more specific marker of susceptibility and that the association of both markers is due to the fact that they are products of closely linked genes. But what is more important than the fact that HLA genes are linked to diabetes is that HLA haplotypes are no longer simply undefined genetic markers. It has been shown that the polymorphisms of the DQ molecules are critical for high-affinity recognition of autoantigens (eg, islet cell antigens) by TCRs. HLA-DQ structure analysis suggests that the lack of aspartic acid at position 57 (Asp^{57}) on the DQ β chain allows the autoantigen (processed peptide) to fit better in the antigen-binding groove formed by this molecule. On the contrary, the presence of Asp^{57} allows the formation of a salt bridge with a conserved arginine at position 76 on the DQ α chain, preventing the accommodation of the immunogenic peptide recognized by the TCR. Several autoimmune diseases have been linked to HLA-DQβ1 genes, including type 1 diabetes, celiac disease, bullous pemphigoid, autoimmune hepatitis, and premature ovarian failure, and the structure of the DQβ1 molecule may be the reason for the increased susceptibility. Other candidate genes associated with autoimmune endocrinopathies are discussed further under the single and polyglandular syndromes.

ENVIRONMENTAL FACTORS IN AUTOIMMUNITY

Environmental factors also play a critical role in the pathogenesis of autoimmune disease. The strongest evidence for this statement comes from studies of monozygotic twins, which show that concordance rates for autoimmune disorders are imperfect (never 100%). As mentioned earlier, in type 1 diabetes, identical twins show less than 50% concordance.

The environmental factors thought to have greatest influence on disease development include infectious agents, diet, and toxins. In type 1 diabetes, viruses have been strong suspects. Up to 20% of children prenatally infected with rubella develop type 1 diabetes. Children with congenital rubella also have an increased incidence of other autoimmune disorders, including thyroiditis and dysgammaglobulinemia. The mechanisms by which these pathogens may induce autoimmune responses include molecular mimicry and direct tissue injury. The hypothesis of molecular mimicry suggests that immune responses directed at infectious agents can cross-react with self antigens, causing tissue or organ destruction. Support for this concept is found in well-known clinical syndromes such as rheumatic fever (immune responses directed against streptococcal M protein seem to cross-react with cardiac myosin, inducing clinical myocarditis). In autoimmune diabetes, the best-studied example of molecular mimicry is the B4 coxsackievirus protein P2-C. Coxsackie B4 virus has also been epidemiologically implicated in the development of type 1 diabetes. There is a striking amino acid sequence similarity between P2-C viral protein and the enzyme glutamic acid decarboxylase (GAD), found in pancreatic β cells (see Autoimmune Aspects of Type 1 Diabetes, discussed later).

The importance of diet in the development of autoimmune diseases remains controversial. An association between early exposure to cow's milk proteins and the risk of type 1 diabetes has been observed in several epidemiologic studies. For example, one study demonstrated that primary immunity to insulin is induced in infancy by oral exposure to cow's milk insulin, but the relevance of this observation is still unknown. On the other hand, selected antigens (from bovine serum albumin to porcine insulin) have been administered orally to mice with a broad spectrum of autoimmune disorders, including nonobese diabetic (NOD) mice, with favorable outcomes. Those data in mice were so compelling that oral tolerance trials in humans have been conducted or are ongoing. Unfortunately, the results of already completed trials in other autoimmune diseases have been disappointing. Three large, randomized, controlled trials designed to delay or prevent type 1 diabetes—the two Diabetes Prevention Trial (DPT-1 and -2) and the European Diabetes Nicotinamide Intervention Trial—have failed to demonstrate a treatment effect. Thus, it should not be concluded that it is impossible to delay or prevent type 1 diabetes; rather, it may require testing of more potent interventions or combinations of therapies, guided by better understanding of the immunopathogenesis of the disease, to demonstrate attenuation or amelioration of the destructive immune process leading to type 1 diabetes.

SINGLE-GLAND AUTOIMMUNE SYNDROMES

Organ-specific autoimmune endocrine disorders may present as single entities or may cluster in polyendocrine syndromes. Most endocrine glands are susceptible to autoimmune attack. Some are affected more frequently than others (see Table 2–1).

AUTOIMMUNE ASPECTS OF THYROID DISEASE

Autoimmune thyroid disease can present in a polarized fashion with Graves disease (thyroid hyperfunction) at one end and Hashimoto thyroiditis (thyroid failure) at the other. This functional subdivision is clinically useful. However, both diseases have a common autoimmune origin.

Genes and Environment

Major susceptibility genes in autoimmune thyroid disease have yet to be identified. Although certain HLA alleles (mainly HLA-DR3 and DQA1*0501) have been shown to be present more frequently in Graves disease than in the general population, this association has frequently been challenged. In fact, no consistent association has been found between Graves disease and any known HLA polymorphism. Furthermore, the risk of developing Graves disease in HLA-identical siblings (7%) is not significantly different from that in control populations. HLA-DR5, -DR3, -DQw7 in Caucasian, HLA-DRw53 in Japanese, and HLA-DR9 in Chinese patients were found to be associated with Hashimoto thyroiditis. However, genetic linkage between Hashimoto thyroiditis and a specific HLA locus has not been demonstrated consistently either. Overall, the HLA loci are likely to provide less than 5% of the genetic contribution to autoimmune thyroid disease, confirming the relative importance of non-HLA-related genes in susceptibility. For example, it has been shown that the inheritance pattern of autoantibodies to thyroperoxidase (TPO) is genetically transmitted. Other candidates are currently under study. However, autoimmune thyroid disease linkage to CTLA-4, HLA, IgH chain, TCR, thyroglobulin (Tg), TPO, and thyrotropin receptor (TSH-R) genes has been excluded. Using positional genetics of a candidate gene, Graves disease susceptibility was mapped to a noncoding 6.13 kb 3′ region of CTLA-4, the common allelic variation of which was correlated with lower messenger RNA levels of the soluble alternatively spliced form of CTLA-4 (sCTLA-4). sCTLA-4 is known to be present in human serum. It can bind CD80/86 molecules on APCs and inhibit T-cell proliferation *in vitro*. The reduction in the level of sCTLA-4 could potentially lead to reduced blocking of CD80/86, causing increased activation through CD28 of autoreactive T cells.

An important environmental factor influencing the natural history of autoimmune thyroid disease is that of iodine intake (dietary, or present in drugs such as amiodarone or in x-ray contrast media). There is considerable evidence that iodine adversely affects both thyroid function and antibody production in those with occult or overt autoimmune thyroid disease.

Autoimmune Response

In Graves disease, thyrocytes are the differentiated carriers of TSH-Rs and the target cells of autoantibodies and probably the autoimmune response. The development of autoantibodies that functionally stimulate the TSH-R mimicking the action of TSH was the first example of antibody-mediated activities of a hormone receptor in humans. Autoantibodies that may stimulate the calcium-sensing receptor (CaSR) (another G-protein–coupled receptor) and signal the inhibition of PTH production have been described in autoimmune hypoparathyroidism. Similarly, stimulating antibodies that bind to the adrenocorticotropin (ACTH) receptor may be involved in the pathogenesis of primary pigmented nodular adrenocortical disease (also referred to as nodular adrenal dysplasia).

In Graves disease, antibodies to the TSH-R present with different types of activity. Thyroid-stimulating immunoglobulins (TSIs), the cause of the hyperthyroidism, are detected by a bioassay that measures cAMP production in a cell line that expresses TSH-Rs. TSH-R autoantibodies (stimulating, blocking, or neutral) can be identified by their ability to prevent TSH binding to the TSH-R (TSH-binding inhibition immunoglobulins [TBII]). No direct immunoassay for the measurement of TSH-R autoantibodies is available yet, and its development may be difficult because TSH-R autoantibodies are present at very low concentrations in patients with the disease.

A particular feature of Graves disease is its early clinical presentation. Unlike other autoimmune endocrinopathies (type 1 diabetes, Hashimoto thyroiditis, autoimmune Addison disease), in which much of the target organ has to be destroyed before the disease is manifested, Graves hyperthyroidism often presents with an enlarged and active gland. Minimal lymphocytic infiltration is present when hyperthyroidism (due to the presence of TSH-R-stimulating antibodies) develops. This unique feature may ultimately allow early immune intervention in preference to current ablative therapeutic options.

Another peculiar feature of Graves disease is the helper T-cell response observed in this disease. The activation of antibody-producing B cells by T_H lymphocytes in Graves disease is well recognized. At present, a prevailing concept of human autoimmunity suggests that, as in acute allograft rejection, "deviation" toward a T_{H1}/T_{H17} response dominates its pathogenesis. Counter-deviation toward T_{H2} is thought to be a consequence of tolerance induction and has been postulated as a potential therapeutic approach. Graves disease seems to challenge that concept. Analysis of TSH-R-specific T-cell clones from patients with Graves disease has provided direct evidence for polarization of T_H responses; however, instead of T_{H1} deviation, T_{H0} and T_{H2} responses have been observed. As mentioned before, T_{H1} cells, which regulate cell-mediated responses, secrete mainly IFN-γ and small amounts of IL-4. In contrast, T_{H2} cells that regulate antibody production (such as TSH-R autoantibodies in Graves disease) preferentially produce IL-4 and little IFN-γ. T cells expressing both IL-4 and IFN-γ are known as T_{H0} cells. These experimental results suggest that in Graves disease T_{H0} to T_{H2} cell responses appear to be dominant. Hence, in human autoimmunity, Graves disease appears to be an exception to the usual T_H cell pattern.

In Hashimoto thyroiditis, the hallmark of the humoral immune response is the presence of autoantibodies to TPO. Although the effector mechanism for TPO (or thyroglobulin [Tg]) autoantibodies is still controversial, under special circumstances (at least *in vitro*) the autoantibodies are themselves cytotoxic agents or activators of cytotoxic T lymphocytes. Furthermore, in secondary T-cell responses, antibodies may play a critical role in antigen processing or presentation to T cells. In short, macrophages internalize (and subsequently process) antigen by phagocytosis and antigen-antibody complex uptake via Fc receptors. B cells have membrane-bound antibodies (B-cell receptors [BCRs]) which provide a much more powerful system for antigen capture. Indeed, recombinant TPO-specific membrane-bound autoantibody captures antigen and allows presentation efficiently. Antibody binding also modulates antigen processing of immune complexes, enhancing or suppressing the presentation of different

T-cell peptides. Hence, APCs (internalizing immune complexes through Fc receptors) and B cells (capturing antigen through BCRs) can influence the secondary T-cell response that perpetuates autoimmune disease. The potential role of autoantibodies in modulating presentation of T-cell determinants in thyroid (and diabetes) autoimmunity is being explored.

Animal Models of Autoimmune Thyroid Disease

The classic immunologic approach to development of an animal model of an autoimmune disease is to immunize the animal with soluble antigen in adjuvant. For autoimmune thyroid disease, the induction of thyroiditis in rabbits using human Tg was one of the earliest attempts to do this—by Rose and coworkers in 1956. In subsequent studies, mice immunized with human or murine Tg developed experimental autoimmune thyroiditis. Immunization with TPO (human or porcine) induces thyroid autoantibodies and, as in the case of Tg, causes thyroiditis to develop in particular MHC strains of mice. However, unlike spontaneous thyroiditis in chickens, none of the immunized mouse models of thyroiditis develop hypothyroidism.

In 1996, Shimojo and coworkers developed a mouse model that clearly mimics some of the major features of Graves disease. This was achieved by the ingenious approach of immunizing mice with fibroblasts stably transfected with the cDNA for the human TSH-R and syngeneic MHC class II (Figure 2–7). Most of the animals had moderately high TBII activity in their sera, and about 25% were clearly thyrotoxic, with elevated T_4 and T_3 values, detectable TSI activity, and thyroid hypertrophy. For the first

time, therefore, an animal model was established in which a significant number of affected subjects have the immunologic and endocrinologic features of Graves hyperthyroidism. More recently, other models have become available. The general rule for induction of an antibody response to the TSH-R in the form of TSI and consequent Graves disease appears to be the need to express the antigen in a native form in an MHC class II carrying cell. Thus, TSH-R-transfected B cells (M12 cell line), TSH-R-adenovirus-infected dendritic cells, and even naked TSH-R DNA or TSH-R adenovirus parenterally delivered and probably captured and expressed by MHC class II expressing cells, have been used to induce TSI and Graves-like disease. However, the focal thyroiditis that accompanies human Graves, as well as the extrathyroidal manifestations that define the disease, have never been reliably reproduced in any of these models. Nevertheless, these models open up new ways of investigating the pathogenesis of Graves disease.

AUTOIMMUNE ASPECTS OF TYPE 1 DIABETES

Most type 1 diabetes results from autoimmune destruction of pancreatic β cells in a process that can span several years. This results in glucose intolerance and clinical disease when the majority of β cells have been destroyed. The destruction is marked by circulating antibodies to pancreatic β cells and by massive infiltration of mononuclear lymphocytes into the islets of Langerhans while pancreatic β cells remain. The lymphocytes slowly disappear when the β cells are gone. Although insulin is available for replacement therapy, type 1 diabetes remains a chronic disorder of major socioeconomic impact, especially because it mainly afflicts the young. Elucidation of the molecular mechanisms underlying this destruction—and the development of methods to prevent autoimmunity—may ultimately lead to effective treatment. Such developments, however, require animal models of type 1 diabetes that closely resemble the disease in humans.

Genes and Environment

The susceptibility to develop type 1 diabetes is associated with certain alleles of the MHC class II locus that have been statistically linked to a variety of autoimmune disorders. The most recent analyses indicate that in Caucasians, HLA-DR3, DQ2 (DQB1*0201) and HLA-DR4 (DRB1*0401), DQ8 (DQB1*0302) haplotypes are most strongly associated with type 1 diabetes. In Asian populations, DRB1*0405 is the major susceptibility haplotype. In contrast, the DR2, DQ6 (DQB1*0602) haplotype is negatively associated with type 1 diabetes. More importantly, susceptibility requires both HLA-DQ β chain alleles to be negative for Asp[57] in the amino acid sequence. Studies of different populations have shown a linear relationship between the incidence of type 1 diabetes and the estimated frequency of homozygous absence of Asp[57].

Non-HLA candidate genes consistently associated with type 1 diabetes include the "variable number of tandem repeats" (VNTR)

FIGURE 2–7 Animal model for Graves disease. This first animal model of Graves-like disease was achieved by injecting AKR/N mice with syngeneic (MHC-identical) fibroblasts dually transfected with mouse MHC class II (H2-k) and human TSH-R cDNA. About 25% of the animals developed endocrinologic (hyperthyroidism) and immunologic (TSI, TBII) features of Graves disease.

polymorphisms in the insulin gene and the CTLA-4 gene (CD152). The VNTR polymorphisms are located adjacent to defined regulatory sequences that influence insulin gene expression. Of immunologic importance, CTLA-4 gene (see Immune Recognition and Response, discussed earlier) is the other non-HLA candidate gene consistently found to be associated with type 1 diabetes.

Although environmental factors definitely play a role in the development of type 1 diabetes (eg, Coxsackie B4 virus, mumps virus, rubella virus, Kilham rat virus in the bio breeding [BB]-rat; or cow's milk formula exposure), more studies are needed to establish a definite etiologic link (see also Genetic and Environmental Factors in Autoimmunity earlier).

Autoimmune Response

The autoantibodies associated with β cell destruction can be present up to several years before the clinical onset of disease and are thus excellent markers of disease risk. Furthermore, they have served as important tools to identify human pancreatic β cell autoantigens. In 1990, Baekkeskov and coworkers identified a 64-kDa islet cell protein as the smaller isoform of the enzyme that synthesizes γ-aminobutyrate (GABA): glutamic acid decarboxylase (GAD65). This autoantigen was shown to be recognized by 70% to 80% of prediabetic and newly diagnosed type 1 diabetic patients' sera. A second component of the 64-kDa antigen was shown to be a putative tyrosine phosphatase, termed IA-2. IA-2 is recognized by 60% to 70% of prediabetic and newly diagnosed type 1 diabetic patients. Together, GAD65 and IA-2 autoantibodies detect over 90% of individuals who develop type 1 diabetes and can be used to detect individuals at risk several years before the clinical onset of disease.

Although autoantibody responses to GAD65 are not easily detected, there is strong evidence to suggest that GAD65 is an important T-cell autoantigen in the NOD mouse. Thus, GAD65 is the earliest known target of the autoimmune T-cell response in the NOD mouse. Administration of the protein in a tolerogenic form prevents disease in NOD mice. In contrast, induction of tolerance to other potential autoantigens in this model (such as carboxypeptidase H and hsp60) does not prevent disease. The NOD mouse does not develop autoimmunity to the IA-2 molecule and thus distinguishes itself from the human disease with regard to this target antigen (see Models, discussed later).

Insulin is a third well-characterized autoantigen in type 1 diabetes. Insulin autoantibodies can be detected in about 50% of newly diagnosed children with type 1 diabetes. Insulin-specific T-cell clones can transfer disease in the NOD mouse. Furthermore, administration of whole insulin, insulin B chain, or an insulin peptide epitope in a tolerogenic form can protect against disease in NOD mice. Because animals receiving insulin or insulin B chain continue to have intra-islet insulitis—in contrast to young NOD mice treated with GAD65 in a tolerogenic way—it has been suggested that insulin reactivity is more distal in disease progression. Additional but less well-characterized proteins have been implicated as targets of autoantibodies in type 1 diabetes in humans.

Autoantibodies, although they are good markers of disease, do not seem to be directly involved in destruction of pancreatic β cells. Adoptive transfer of diabetes to NOD mice with spontaneous, combined immunodeficiency (NOD-SCID) lacking B cells, can be mediated by T cells alone. However, because β-cell-deficient NOD mice do not develop disease, it is possible that B lymphocytes function as important APCs in the islet to perpetuate an ongoing autoimmune response and thus are essential for presentation of rare antigens such as GAD65 and IA-2. (See also autoimmune response in the section on Autoimmune Aspects of Thyroid Disease, discussed earlier.)

An important question is whether GAD65, IA-2, and insulin are major target antigens of T-cell mediated β-cell destruction that results in type 1 diabetes in humans. Proliferative and cytotoxic T-cell responses to GAD65 are detected in the peripheral blood of newly diagnosed type 1 diabetes patients, but their pathogenicity has not been addressed. Induction of neonatal tolerance to GAD65 specifically prevents diabetes in the NOD mouse model. The role of IA-2 in destructive autoimmunity to the pancreatic β cell in humans is suggested by the high-predictive value of IA-2 antibodies for clinical onset of diabetes.

Both GAD65 and IA-2 are neuroendocrine proteins, which are expressed at significant levels in the brain and β cell. Stiff-man syndrome—a very rare neurologic disorder in humans with a high coincidence of diabetes—is characterized by a strong autoantibody response to GAD65, the titer of which is several orders of magnitude higher than in diabetes. It has been suggested that impairment of GABA-secreting neurons in stiff-man syndrome is mediated by GAD65 autoantibodies, whereas development of type 1 diabetes is associated with a cellular immune response to GAD65. The low incidence of stiff-man syndrome compared with type 1 diabetes (only one in 10^4 type 1 diabetic patients develops stiff-man syndrome, whereas 40% of stiff-man syndrome patients develop type 1 diabetes) probably reflects in part the protection of GABAergic neurons by the blood–brain barrier and the absence of MHC class II antigen expression in normal neurons. The cellular localization of IA-2 expression in brain is not known, and there are no known disorders of the central nervous system that involve autoimmunity to IA-2.

In the NOD mouse, the destruction of pancreatic β cells requires both the CD4 T-helper (T_H) cells and CD8 cytotoxic (T_C) cells. Whereas T_H cells seem to be required for the development of an autoimmune response to the islets and generation of intrainsulitis, T_C cells are probably the effector cells of β-cell destruction. Furthermore, there is evidence that in the CD4 lineage, the T_{H1} subset is important for development of disease in the NOD mouse. T_{H1} cells are induced by IL-12 and are biased toward secreting IFN-γ and IL-2. In contrast, there is evidence that the T_{H2} cytokine IL-4 exerts a dominant-negative effect on diabetes progression in the NOD mouse. In humans, low autoantibody titers associated with type 1 diabetes and high titers associated with a protective haplotype (DR2) suggest that a strong T_{H2} response can be inhibitory for β-cell destruction. A role for T_{H1} cells in human disease is also suggested by results of cytokine profiles of peripheral human NK cells in identical twins which are discordant for the development of diabetes. This is different from

the observed T_H responses in Graves disease (see Autoimmune Aspects of Thyroid Disease discussed earlier).

It has been suggested that it is not the presence of autoantibodies to GAD65 but the absence of the corresponding anti-idiotypic antibodies that defines type 1 diabetes. Anti-idiotypic antibodies bind to the idiotype (binding region) of other antibodies. Investigators found that while diabetes patients are positive for GAD65 antibodies because they lack certain anti-idiotypic antibodies, healthy individuals are negative for GAD65 antibodies because of the very presence of anti-idiotypic antibodies directed against GAD65 antibodies in their serum.

Animal Models of Autoimmune Diabetes Mellitus

The NOD mouse has been invaluable for studies of molecular mechanisms of autoimmunity directed toward the pancreatic β cells and the development of diabetes. It has several features, however, which distinguish it from the human disease. The incidence of diabetes is two to three times higher in female than in male NODs, whereas in humans there is a slight preponderance of type 1 diabetes in males. Furthermore, while the induction of organ-specific autoimmunity and inflammation in humans may be caused by human pathogens or toxins, autoimmunity seems to be the default mechanism in the NOD mouse. Thus, mice in clean, pathogen-free environments have a high incidence of disease, whereas a variety of regimens that stimulate the immune system of the mouse, such as viral infection or injection of complete Freund adjuvant, prevent disease. To date, more than 125 treatments for successful prevention or delay of diabetes in the NOD mouse have been identified, but none have been identified for humans.

The BB rat develops spontaneous T-cell-mediated diabetes. The BB-rat disease is significantly different from the human disease in that it is accompanied by autoantibodies to lymphocytes and a severe lymphocytopenia, which is essential for development of β-cell autoimmunity and diabetes in this model.

In an attempt to develop better models of diabetes, "humanized" transgenic mice that express diabetes-prone **human MHC class II** molecules were developed. Since these animals did not develop spontaneous diabetes, they were backcrossed into the NOD background. However, backcrossing to NOD once again prevented the development of diabetes. Other animal models of type 1 diabetes, some of them *carrying* **human MHC class II** diabetes-susceptibility genes, were developed by expression of ectopic molecules in the islets using the rat insulin promoter (RIP). In some of these models, diabetes needed to be induced by immunization with, for example, insulin peptides or lymphocytic choriomeningitis virus. However, none of these models fully reflect the human disease in that the immune attack was initiated against target human β-cell autoantigen(s) in an MHC class II–restricted fashion, without the need for *aberrant protein(s)* (foreign to the pancreatic β-cell) expression.

Although some of the models of type 1 diabetes described have been very useful for studies of basic immunologic mechanisms associated with pancreatic β-cell autoimmunity, other models of type 1 diabetes closer to what occurs in humans are needed if immunoprevention and immunomodulatory techniques are to be tested. At a minimum, human susceptibility genes and human target antigens need to coexist in an animal model to mimic human autoimmune responses.

AUTOIMMUNE ASPECTS OF OTHER ENDOCRINOPATHIES

Autoimmune Adrenal Failure

Autoimmune Addison disease seldom develops as a single-gland syndrome. In about 50% of cases, the disease is associated with other gland and organ failure. Anderson and coworkers described the existence of adrenal-specific autoantibodies for the first time in 1963. Using immunofluorescence techniques on sections of human, bovine, or monkey adrenals, antibodies specifically recognizing the adrenal cortex (ACA) were described. Steroid-producing cell autoantibodies (SCA) reactive with cells of the adrenals, gonads, and placenta were described by Anderson and coworkers in 1968. SCAs are detected predominantly in ACA-positive patients with Addison disease who have premature ovarian failure in the context of autoimmune polyendocrine syndrome type I (APS-I; see Autoimmune Polyendocrine Syndromes, discussed later).

Steroid 21-hydroxylase has been identified as a major adrenal autoantigen in ACA-positive patients with Addison disease. Using a sensitive assay based on the immune precipitation of radiolabeled recombinant 21-hydroxylase, workers in one study reported positive testing in sera from 72% of patients with isolated Addison disease, 92% of patients with APS-1, 100% of patients with APS-2, and 80% of patients who were positive for ACA by immunofluorescence but did not have clinically overt Addison disease (apparently healthy blood donors showed 2.5% positivity) (Table 2–2). Another study measured ACA in 808 children with organ-specific autoimmune diseases without adrenal insufficiency. ACAs were detectable in 14. Ten of these ACA-positive children (also positive for 21-hydroxylase antibodies) and 12 ACA-negative children were prospectively followed with adrenocortical function testing and antibodies. Overt Addison disease developed in 9 (90%) ACA/21-hydroxylase antibody-positive children within 3 to 121 months, and the one remaining

TABLE 2–2 Adrenal autoantibodies in different syndromes.

Autoantibodies	Addison Disease (%)	APS-1[a] (%)	APS-2[b] (%)	ACA(+)[c] (%)
21-Hydroxylase	72	92	100	80
17α-Hydroxylase	5	55	33	20
P450scc	9	45	36	20

[a]APS-1: Autoimmune polyglandular syndrome type 1: Autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy.

[b]APS-2: Autoimmune polyglandular syndrome type 2: Adrenal insufficiency, thyroid disease, and diabetes mellitus.

[c]ACA(+): Adrenal cortex antibody-positive without clinically overt Addison disease.

child had subclinical hypoadrenalism throughout an extra 24-month observation period. The progression to adrenal failure was not related to ACA titer, sex, baseline adrenal function (subclinical insufficiency vs normal function), type of associated autoimmune disease, or HLA status. Although ACA 21-hydroxylase antibodies appear to be highly predictive in children, in adults the cumulative risk of developing Addison disease in patients with other organ-specific autoimmune diseases and positive ACA 21-hydroxylase antibodies is about 32%. Steroid 17α-hydroxylase is another adrenal autoantigen. 17α-hydroxylase antibodies were found in 5% of patients with isolated Addison disease, 55% of patients with APS-1, 33% of patients with APS-2, and 20% of sera from patients who were positive for ACA but did not have clinically overt Addison disease (see Table 2–2). Antibodies against another adrenal autoantigen, cytochrome P450 side-chain cleavage enzyme (P450scc), were found to be present in 9% of patients with isolated Addison disease, 45% of patients with APS-1, 36% of patients with APS-2, and 20% of sera from patients who were positive for ACA but did not have clinically overt Addison disease (see Table 2–2). The prevalence of P450scc antibodies in these groups of patients was always lower than that of 21-hydroxylase antibodies but similar to that of 17α-hydroxylase antibodies. Furthermore, almost all sera that were positive for 17α-hydroxylase or P450scc antibodies were also positive for 21-hydroxylase antibodies. In addition, a comparison of SCAs measured by immunofluorescence with 17α-hydroxylase and P450scc antibody measurements suggested that 17α-hydroxylase and P450scc are the major components of the SCA antigen just as 21-hydroxylase is the major component of ACA antigen.

Overall, immune responses in autoimmune adrenal disease may involve other antigens, but reactivity to the three described, particularly 21-hydroxylase, appears to predominate. Although inhibition of enzymatic activity by these antibodies has been shown *in vitro*, no clear relationship to the pathogenesis of the clinical syndrome has yet been established.

Autoimmune Oophoritis and Orchitis

An autoimmune origin for premature ovarian failure with concomitant Addison disease or oophoritis can be based on the following human and animal data: (1) the presence of autoantibodies to SCA in most cases, (2) the characterization of shared autoantigens between the adrenals and the ovaries (ie, 17α-hydroxylase and P450scc), (3) the histologic features of the ovaries (lymphocyte and plasma cell infiltrate involving steroid-producing cells), and (4) animal models of the syndrome. There is some evidence of autoimmunity in idiopathic premature ovarian failure not associated with Addison disease (cellular immune abnormalities, presence of various ovarian antibodies in some patients, and associations with type 1 diabetes and myasthenia gravis); however, the absence of histologic confirmation makes the autoimmune pathogenesis less credible.

Less is known about the autoimmune pathogenesis of human orchitis. Animal models, however, have shown that infectious or traumatic injury to the testes can induce autoimmune responses in this immune-privileged tissue (defined as sites where antigens are not presented to the host immune system; see Tolerance, discussed earlier).

Autoimmune Hypophysitis

Autoimmune hypophysitis (also called lymphocytic hypophysitis) should be considered in the differential diagnosis of pituitary abnormalities in women (8:1 female:male ratio) during the latter half of pregnancy and in the first 6 months postpartum, as well as in patients with coexisting autoimmune disorders, for example, thyroiditis, adrenalitis, autoimmune hypoparathyroidism, or atrophic gastritis. More than 380 cases have been described since the original report in 1962. Antipituitary antibodies have been detected in a minority of patients. Owing to the lack of markers for the disease, the diagnosis can only be confirmed with histologic examination. Nevertheless, because of the usually transient endocrine and compressive features of this condition, conservative management based on clinical suspicion may prevent the consequences of unnecessary pituitary surgery. Granulomatous hypophysitis—another form of autoimmune hypophysitis—appears to have a similar autoimmune pathogenesis but more commonly affects postmenopausal women and men. The presence of T regs in this form of hypophysitis, however, makes the autoimmune pathogenesis less clear.

Autoimmune Hypoparathyroidism

Autoimmune hypoparathyroidism, also called idiopathic hypoparathyroidism, is one of the major components of APS type 1 (APS-1; see next section). It also presents as a sporadic disease, sometimes associated with Hashimoto thyroiditis in women. The fact that autoimmune hypoparathyroidism presents in association with other autoimmune diseases and also the presence of autoantibodies reactive with parathyroid tissue in many affected patients suggests an autoimmune pathogenesis. Parathyroid autoantibodies have been reported to show a complement-dependent cytotoxic effect on cultured bovine parathyroid cells. At least one major parathyroid autoantigen has been identified as the CaSR. The CaSR is of great importance in the regulation of parathyroid hormone secretion and renal tubular calcium reabsorption. This receptor is a member of the 7-membrane-spanning domain G protein–coupled receptor family. It is also expressed in thyroid C cells, the pituitary, the hypothalamus, and in other regions of the brain. The relationship of the autoimmune response directed against the receptor to the pathogenesis of the disease is not clear. However, antibody-mediated stimulation of the CaSR with consequent inhibition of PTH synthesis and secretion has been suggested. The prevalence of the CaSR antibodies in clinically diagnosed idiopathic hypoparathyroidism was found to be 56% in one study. Measurement of these antibodies may have value in predicting the development of autoimmune hypoparathyroidism in patients with autoimmune endocrinopathies who are at risk. Furthermore, hypercalcemia in a patient with multiple autoimmune disorders, responsive to glucocorticoids, has been described as secondary to the presence of a blocking IgG4 autoantibody

directed against the CaSR and apparently capable of blocking the inhibitory actions of the ligand calcium (see also Chapter 8).

AUTOIMMUNE POLYENDOCRINE SYNDROMES

Associations of multiple autoimmune endocrine disorders have been classified in different syndromes. APS type 1 and type 2 (APS-1 and -2) can be clearly separated clinically (Table 2–3). Some authors have attempted to subdivide APS-2 (ie, APS-2 and -3) on the basis of the association of some autoimmune disorders but not others. Little information is gained, however, by making this subdivision in terms of understanding pathogenesis or prevention of future endocrine failure in patients or their relatives. Other autoimmune associations, not always described in syndromes, are also classically recognized. Vitiligo, for example, seems to

accompany multiple autoimmune endocrinopathies. There is now convincing evidence of linkage between *NALP1* (*NACHT leucine-rich-repeat protein 1*), a gene involved in immune regulation, and the presence of vitiligo associated with at least one endocrine autoimmune disease including but not limited to type 1 diabetes, Addison disease, and thyroiditis.

AUTOIMMUNE POLYENDOCRINE SYNDROME 1 (APS-1)

APS-1 is an autosomal recessive disorder with 25% incidence among siblings of affected individuals. Also known as APECED, or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, APS-1 is characterized by the triad of chronic mucocutaneous candidiasis, autoimmune hypoparathyroidism, and adrenal insufficiency (only two are required in the index case for the

TABLE 2–3 Comparison of the different components of autoimmune polyendocrine syndromes.

Characteristics	Type 1	Type 2
Inheritance	Autosomal recessive	Polygenic
Genetic association or linkage	Linked to AIRE	Some HLA association
Gender	Equal distribution	Female preponderance
Age at onset	Infancy	Age 20-40
Endocrine disorders		
Addison disease	60%-72%	70%
Hypoparathyroidism	Common (79%-96%)	Rare (late onset)
Autoimmune thyroid disease	Less frequent (about 5%)	More frequent (about 70%)
Type 1 diabetes	14% (lifetime)	>50%
Primary hypogonadism	60% female, 14% male	About 5%
Hypophysitis	Not reported	Reported
Dermatologic		
Chronic mucocutaneous candidiasis	Often at onset (about 100%)	Not reported
Alopecia	Common (about 29%)	Reported
Vitiligo	About 13%	About 5%
Dermatitis herpetiformis	Not reported	Reported
Gastrointestinal		
Celiac disease	None (only steatorrhea)	Present in 2%-3%
Autoimmune hepatitis	About 12%	Not reported
Hematologic		
Pernicious anemia	About 13%	As common as in APS-1
Pure red cell hypoplasia	Reported	Not reported
Idiopathic thrombocytopenic purpura	Not reported	Reported
Ectodermal		
Enamel hypoplasia	All reported	Not reported
Nail dystrophy		
Tympanic membrane calcification		
Neurologic		
Myasthenia gravis	None reported	All reported
Stiff-man syndrome		
Parkinson disease		
Other		
Asplenism	Reported	Not reported
Keratopathy	Reported	Not reported
Progressive myopathy	Reported	Not reported
IgA deficiency	Not reported	Reported
Serositis	Not reported	Reported
Idiopathic heart block	Not reported	Reported
Goodpasture syndrome	Not reported	Reported

diagnosis, and only one in the siblings). Chronic mucocutaneous candidiasis (involving oral mucosa and nails or, less frequently, the esophagus) is usually manifested as the initial problem early in life. In most individuals, the development of autoimmune hypoparathyroidism, a major clinical phenotype, usually follows. Specifically for hypoparathyroidism, the presence of antibodies to NALP5 (NACHT leucine-rich-repeat protein 5), a gene highly expressed in parathyroid and ovary, have been described. In one study these antibodies were detected in 49% of patients with known APS-I and hypothyroidism (see also Chapter 8). Addison disease is another component of the triad that can manifest prior to, concomitantly with, or following hypoparathyroidism. Lifelong surveillance is important since decades may elapse between the development of one feature of the disorder and the onset of another. There is no female preponderance in this syndrome, and it is not HLA-associated. APS-1 may occur sporadically or in families. The genetic locus responsible for the disease has been mapped to the long arm of chromosome 21 (21q22.3). The haplotype analysis of this region in different populations has shown that APS-I is linked to different mutations in a gene identified as the autoimmune regulator (AIRE). AIRE encodes a putative nuclear protein with transcription factor motifs (including two zinc finger motifs). It is expressed in different tissues but particularly in the thymus. The mechanism by which mutations of this putative transcription factor lead to the diverse manifestations of APS-1 is still being defined. In mice, however, the absence of the analogous protein "aire" influences ectopic expression of peripheral tissue antigens in thymic medullary epithelial cells (MECs), resulting in the development of an autoimmune disorder similar to APS-1 and establishing aire/AIRE as an important factor in the induction of central tolerance. Aire has been reported to promote the perinatal generation of a distinct compartment of Foxp3+CD4+ T reg cells, which stably persists in adult mice. This population has a role in maintaining self-tolerance, a transcriptome and an activation profile distinguishable from those of T regs produced in adults. This concept adds to the notion of a developmentally layered immune system. Other immune response-related genes as well as environmental factors probably play a role in development of the syndrome. Several studies of large cohorts of patients from different ethnic backgrounds have reported the appearance of chronic candidiasis at different sites in all patients. Moreover, the development of classic autoimmunity varies greatly between patients; however, the development of anticytokine-specific humoral immune responses appears to serve a more common characteristic of the disease. In one study, anti-interferon (IFN) antibodies in patients with APS-1 were detected in all Finnish and Norwegian patients with APS-1. The early finding of high-titer autoantibodies against IFNs has created a useful diagnostic test for APS-1. Neutralizing anti-IL-17 autoantibodies in patients with APS-1 have also been described. IL-17 is produced by a subset of T cells, T_{H17} cells, and plays an important part in the response to pathogens, particularly at mucosal surfaces. Additional analysis of IL-17 and IL-22 responses to the presence of Candida albicans antigens showed a marked deficiency in the ability of patients with APS-1 to produce IL-17 and IL-22. These findings raise an intriguing new aspect for the role of anticytokine autoantibodies,

which seem to provide a permissible environment for the development of chronic mucocutaneous candidiasis. Hypoparathyroidism and Addison disease present with similar high frequency (see Table 2–3). The occurrence of the diagnostic triad reportedly presents in 57% of patients. Female hypogonadism, presenting as total or partial failure of pubertal development or as premature ovarian failure in adults, has been reported in up to 60% of patients. Male hypogonadism is less frequent (14%). Type 1 diabetes is not as frequent as in APS-2, but if present, usually develops early (under 21 years of age). Autoimmune hypothyroidism (atrophic thyroiditis) is also less frequent than in APS-2; however, thyroid autoantibodies may be present in many euthyroid patients. Other manifestations are described in Table 2–3. Acute autoimmune hepatitis is reportedly less common than chronic hepatitis, which appears to be present in most individuals. Autoantibodies to aromatic L-amino acid decarboxylase (AADC) are associated with chronic active autoimmune hepatitis and vitiligo, which are found in APS-1. These antibodies, if present, can be helpful in making the diagnosis. Autoantibodies against tryptophan hydroxylase have been associated with gastrointestinal dysfunction in APS-1. Autoantibodies to the H^+-K^+-ATPase and to intrinsic factor are associated with pernicious anemia, and autoantibodies to tyrosinase are associated with vitiligo. Other autoantibodies associated with the single-gland disorders that make up this polyendocrine syndrome have been discussed above.

AUTOIMMUNE POLYENDOCRINE SYNDROME 2 (APS-2)

APS-2 is the most common of the polyendocrine failure syndromes. It affects women in a 3:1 ratio to men. APS-2 is diagnosed when at least two of the following are present: adrenal insufficiency, autoimmune thyroid disease (thyroiditis with hypothyroidism or Graves disease with hyperthyroidism), and type 1 diabetes. Historically, Schmidt (1926) first described the association of Addison disease and thyroiditis. Carpenter and coworkers in 1964 included type 1 diabetes in the syndrome. Other components of APS-2 include the following (see Table 2–3): primary hypogonadism, myasthenia gravis, celiac disease, pernicious anemia, alopecia, vitiligo, and serositis. The most frequent association appears to be with type 1 diabetes (over 50%) and autoimmune thyroid disease (70% in some series). Adrenal insufficiency may be concurrent, may be delayed in onset for up to two decades, or may never manifest. Some diabetic patients (2%-3%) develop celiac disease. Gluten-free diet is usually effective. If the celiac disease is untreated, hypocalcemia (not due to hypoparathyroidism), osteopenia, and occasionally gastrointestinal lymphoma may occur.

Although this syndrome and its components aggregate in families, there is no identifiable pattern of inheritance. Susceptibility is probably determined by multiple gene loci (HLA being the strongest) that interact with environmental factors. Many of the disorders of APS-2 are associated (some genetically linked) with the HLA haplotype identified in single organ disorders. HLA-A1, -B8, -DR3 and -DR4, DQA1*0501, and DQB1*0201 have all been described as associated with APS-2.

MANAGEMENT OF AUTOIMMUNE POLYENDOCRINE SYNDROMES

Hormonal replacement therapy remains the only form of treatment of the APS. The clinical management of these disorders mandates early diagnosis of associated components. Since the age at onset of associated disorders is clinically unpredictable, long-term follow-up is needed. Endocrine disorders are treated as they develop and are diagnosed. Hormonal treatments for the specific gland failures are described elsewhere in this book. However, specific combinations of endocrine organ failure require specific management. For example, thyroxine replacement can precipitate life-threatening adrenal failure in a patient with untreated Addison disease. Furthermore, hypoglycemia or decreasing insulin requirements in a patient with type 1 diabetes may be the earliest symptom/sign of adrenal insufficiency. Hypocalcemia, seen in APS-2, is more commonly due to celiac disease than hypoparathyroidism. Treatment of mucocutaneous candidiasis with ketoconazole in patients with APS-1 may induce adrenal insufficiency in a failing gland (ketoconazole is a global P450 cytochrome inhibitor). These antifungal drugs may also elevate liver enzymes, making the diagnosis of autoimmune hepatitis—requiring treatment with immunosuppressants—more difficult in these patients.

Screening of affected individuals as well as their relatives is the only way of preventing morbidity and mortality. Annual measurement of TSH is recommended as cost-effective in first-degree relatives of patients with type 1 diabetes. Autoantibody measurements may help in the preclinical assessment of several disorders. Complete blood counts, electrolytes, calcium and phosphorus levels, thyroid and liver function tests, blood smears (including RBC indices), and vitamin B_{12}/plasma methylmalonic acid measurements are all recommended in the follow-up of APS-1. For APS-2 patients with type 1 diabetes, thyroid disease and celiac disease coexist with sufficient frequency to justify not only TSH measurement but also screening for endomysial antibodies containing transglutaminase antibodies, which are prevalent in celiac disease.

IMMUNODEFICIENCY, POLYENDOCRINOPATHY, AND ENTEROPATHY, X-LINKED SYNDROME

Another autoimmune polyendocrine failure syndrome, immunodeficiency, polyendocrinopathy, and enteropathy, x-linked (IPEX) syndrome, is characterized by development of overwhelming systemic autoimmunity in the first year of life resulting in the observed triad of watery diarrhea, eczematous dermatitis, and endocrinopathy seen most commonly as type 1 diabetes mellitus. Most children have other autoimmune phenomena including Coombs positive anemia, autoimmune thrombocytopenia, autoimmune neutropenia, and tubular nephropathy. The majority of affected males die within the first year of life of either metabolic derangements or sepsis; a few survive into the second or third decade.

Diagnosis is based on clinical findings. FOXP3 is the only gene currently known to be associated with IPEX syndrome. Approximately 50% of males with IPEX syndrome have mutations identified in FOXP3. Genetic testing is clinically available. FOXP3 is expressed primarily in lymphoid tissues (thymus, spleen, and lymph nodes), particularly in CD4+ CD25+ regulatory T lymphocytes. In mice, it is required for the development and suppressive function of this important T reg population. In humans, it is not expressed at baseline in CD4+ CD25– or CD8+ T cells but is expressed upon T-cell activation. The FOXP3 protein is absent (due to nonsense, frameshift, or splicing mutations) in individuals with severe, early-onset IPEX syndrome. Some individuals with FOXP3 point mutations express a protein that appears to have decreased function, thereby leading to a milder form of the disease. Peripheral blood mononuclear cells from individuals with IPEX syndrome show an excess production of the T_{H2} cytokines IL-4, IL-5, IL-10, and IL-13 and decreased production of the T_{H1} cytokine IFN-γ.

Treatment options include: immunosuppressive agents (eg, cyclosporin A, tacrolimus) alone or in combination with steroids; sirolimus (rapamycin) for persons in whom tacrolimus therapy is toxic or ineffective; granulocyte colony-stimulating factor (G-CSF, filgrastim) for autoimmune neutropenia; nutritional support; and standard treatment of diabetes mellitus and autoimmune thyroid disease. If performed early, bone marrow transplantation (BMT) using nonmyeloablative conditioning regimens can resolve clinical symptoms. If the family-specific mutation is known, FOXP3 sequence analysis in at-risk males can be undertaken immediately after birth to permit early diagnosis and BMT before significant organ damage occurs; otherwise, monitoring at-risk males for symptoms is needed to enable early diagnosis and treatment.

IPEX syndrome is inherited in an x-linked manner. The risk to siblings of the proband depends on the carrier status of the mother. If the mother of the proband is a carrier, the chance of transmitting the disease-causing mutation in each pregnancy is 50%. Males who inherit the mutation will be affected; females who inherit the mutation are carriers and will not be affected. Affected males pass the disease-causing mutation to all of their daughters and none of their sons. Prenatal testing for pregnancies at risk is possible for families in which the disease-causing mutation has been identified.

POEMS SYNDROME (OSTEOSCLEROTIC MYELOMA)

The POEMS (polyneuropathy, organomegaly, endocrinopathy, M spike, skin abnormalities) syndrome, which is frequently seen as a concomitant of Castleman disease (giant cell lymph node hyperplasia), includes a variety of endocrinopathies of the adrenal, thyroid, pituitary, gonads, parathyroids, and pancreas.

The POEMS syndrome displays a number of endocrinopathies in the setting of lymphoproliferative disorders and presumed B-cell dysfunction. Aside from one report in which 2 of 11 patients with monoclonal gammopathy and some form of autoimmunity had POEMS, the endocrinological manifestations of

POEMS are not yet established as autoimmune in origin. When associated with Castleman disease, Kaposi-associated herpes virus (HHV8) may be implicated in the pathogenesis of the lymphoproliferation and the gammopathy.

Two-thirds of patients with POEMS reportedly had at least one endocrine abnormality at presentation. During the course of disease, endocrine abnormalities developed in another 10% of patients with POEMS. Hypogonadism seems to be the most common endocrine abnormality. Elevated levels of follicle-stimulating hormone (FSH) in the absence of primary hypogonadism have been reported. One-third of patients reportedly have erectile dysfunction with low serum testosterone levels. Fourteen percent of patients have hypothyroidism requiring therapy. An additional 12% had mild increases in TSH levels but normal thyroxine levels in one series. Sixteen percent of patients with POEMS have abnormalities of the adrenal-pituitary axis at presentation; with 5% of patients developing adrenal insufficiency later in the course of their disease. Three percent of patients have diabetes mellitus. Serum levels of parathyroid hormone were increased in three of four patients in whom it was measured in one series of 99 POEMS patients. Finally and although still hypothetical for POEMS, autoantibody-mediated mechanisms of disease (Graves disease) have been described in patients with other gammopathies.

The individual practitioner faces a multiplicity of potential diagnoses, limitations in diagnostic capacity, subclinical disease identified by tests rather than by clinical manifestations, and rapid changes in scientific knowledge. The paradigm of clinical decision-making based on the assumption that all that is needed to guide clinical practice is personal experience (however unsystematic), understanding of pathophysiology, and thorough training plus common sense is insufficient to address these challenges. Moreover, the integration of relevant research findings into clinical practice has been haphazard; the lag time between development of scientific knowledge and introduction into practice can be many years, and there is marked variation in practice. A systematic approach based on principles of clinical epidemiology can help address some of these issues. This quantitative approach has formed the primary, albeit not the only, basis of the evidence-based medicine (EBM) movement. This movement posits that understanding certain rules of evidence is necessary to interpret the literature correctly and that physicians who practice based on the above understanding will provide superior care. This chapter summarizes some of the principles of clinical epidemiology and evidence-based endocrinology and some of their limitations.

CLINICAL EPIDEMIOLOGY

Clinical epidemiology consists of the application of epidemiologic principles and methods to problems encountered in clinical medicine. Clinical epidemiology emphasizes a quantitative approach and is therefore concerned with counts of clinical events. Its applications are paramount (1) in diagnostic testing and how the results modify the probability of a particular disorder being present and (2) in treatment decisions in which the potential benefits and harms must be addressed. The techniques of clinical epidemiology have become increasingly important as practitioners confront the complexity of contemporary medical practice.

DIAGNOSTIC TESTING: TEST CHARACTERISTICS

The appropriate choice and interpretation of diagnostic tests, whether biochemical assays, radiologic procedures, or clinical findings, have always been essential to the clinical practice of endocrinology. These tests, when introduced in the medical literature, are accompanied by varying degrees of validation. The clinician's

assessment of the utility of tests, now even more important with the emphasis on cost-effectiveness, can be improved by knowledge of test EBM principles. We review some of these concepts as they apply to diagnosis and management of endocrine disorders, including the topics of test characteristics such as sensitivity and specificity, receiver-operating characteristic (ROC) curves, likelihood ratios, predictive values, and diagnostic accuracy.

The evaluation of endocrine function begins with a clinical question. The more vague the question, the more difficult it is to obtain a clear answer. Part of this step involves a clinical judgment about the likelihood of the disease prior to obtaining a test and its results. This pretest probability is combined with the performance characteristics of the test and its use (sensitivity and specificity, ROC curves, likelihood ratios, predictive values, and diagnostic accuracy) in order for proper interpretation. Variation is inherent in biological systems. Therefore, diagnostic tests must take into account not only variability of the tests themselves and how they are performed but also variability in the populations in whom the tests were developed, both with the disease and without the disease. Key aspects in the analysis of a test include reproducibility (precision) and accuracy. **Reproducibility** describes how close the test comes to producing the same results every time and depends on such factors as intraobserver and interobserver variability (as in the assessment of a physical finding or x-ray) and, in the case of biochemical tests, characteristics such as intra-assay and interassay coefficients of variation (CVs). Although studies utilizing radioimmunoassays and other assays routinely report intra-assay and interassay CVs, few papers publish multiple results performed on the same patient (intra-individual variation). There have also been relatively few studies on the reliability of measurements (ie, the degree of intra-individual variation). One study from 1994 found that the minimum number of replicate measurements necessary to achieve satisfactory reliability of the mean of basal levels was 3 for plasma cortisol and 18 for salivary cortisol. Responses to dynamic tests required fewer replicates to achieve the same reliability (one to two samples).

Reproducibility depends on the conditions under which the test is performed. Clinicians must be aware of the distinction between efficacy and effectiveness when translating published results into practice. As applied to diagnostic testing, efficacy refers to the degree to which the test has been shown scientifically to accomplish the desired outcome. In contrast, effectiveness refers to the degree to which the test achieves this outcome in actual clinical practice. Most large studies have been performed in research venues and thus are efficacy studies, whereas the effectiveness of most tests in practice has not been extensively evaluated. In comparing one's own results with a published report or laboratory normal range, it is important to take into account those conditions (eg, test performed in a hospital vs a physician's office).

Accuracy describes how close the test comes to producing results that are a true measure of the phenomenon of interest; systematic bias of a highly reproducible test may produce the same incorrect result every time. Like reproducibility, accuracy depends on the conditions under which the test is performed; accuracy in the clinical practice setting may differ from that in the experimental setting where many extraneous influences are controlled.

When interpreting a test, the result is usually compared to a normal range. Frequently, the normal range is developed by using a reference population assumed (or preferably shown) to be disease free. For example, when designing a test to be used in the diagnosis of Cushing syndrome, the reference group should be made up of individuals who have clinical features suggestive of Cushing syndrome but who in fact do not have the disorder. However, reference groups may be made up of individuals who are readily accessible and not more appropriate comparisons. It is also important to note that in establishing a normal range based on a Gaussian or normal distribution, encompassing the mean ± two standard deviations, 5% of disease-free individuals have a result outside the limits of normal. (It is important to note that the definition of normal based on a Gaussian distribution of values is only one of a number of definitions of normal. Some others include the one most representative or most common in a class, the one most suited to survival, and the one that carries no penalty [ie, no risk].) Figure 3–1 illustrates a normal range and a range in a population with disease. A result outside normal limits is not equivalent to disease. Moreover, values within the normal range do not necessarily exclude disease. Values in the population of individuals with disease are determined separately, and the overlap with the normal range is assessed.

Sensitivity and Specificity

Ideally, a diagnostic test has no overlap between the results of individuals with the disease and those without the disease. The reality, however, is different. Test characteristics that describe this overlap are sensitivity and specificity, and they are typically illustrated in a 2 × 2 table. As shown in Figure 3–2, sensitivity and specificity are collectively known as **operating characteristics**. Sensitivity refers to the ability to identify correctly individuals with a disease. The sensitivity of a sign or symptom (or diagnostic test) is the proportion of patients with disease who has a positive test result, sign, or symptom. In contrast, specificity refers to the ability to identify correctly individuals without a disease. The specificity of a test is the proportion of healthy patients who have a negative test result or who lack that sign or symptom.

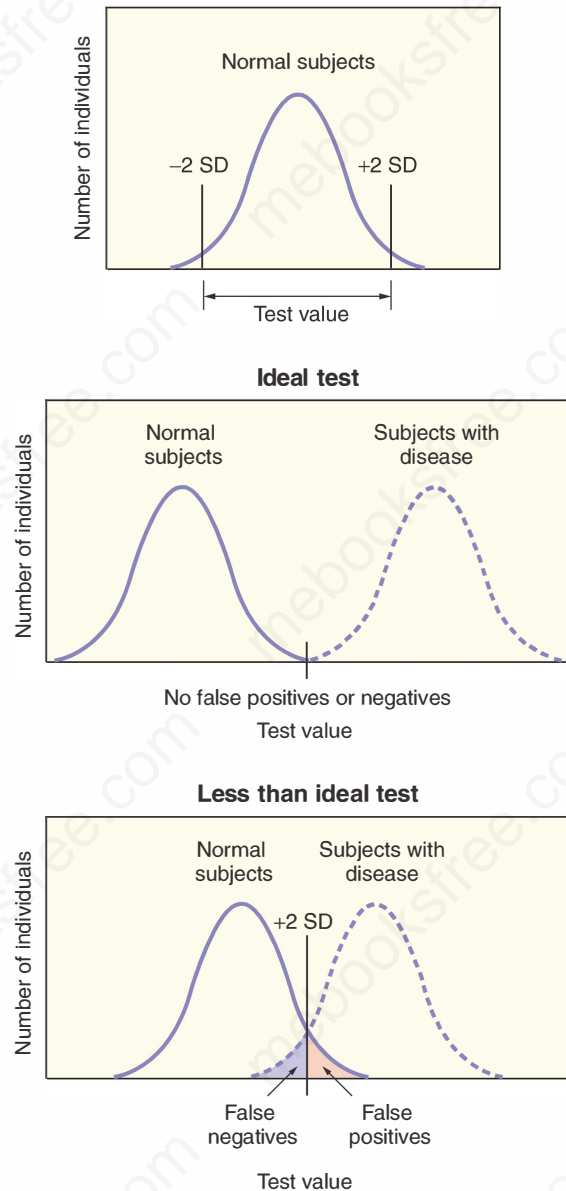
Thus, the **sensitivity** of a test equals the number of individuals with disease who have a positive test (true positive [TP]) divided by the number of individuals with disease (true positives plus false negatives [FN]), whereas **specificity** equals the number of individuals without the disease who have a negative test (true negatives) divided by the number of individuals without disease (true negatives plus false positives [FP]). Sensitivity is sometimes termed **PiD** or positivity in disease, and specificity is sometimes termed **NiH** or negativity in health. In theory, sensitivity and specificity are characteristics of the test itself and not of the patients on whom the test is applied. However, this may not be correct in practice. The sensitivity of a test may be affected by the stage or severity of the disease. The specificity of a test may depend on the characteristics of the reference population. The nature of the groups used to establish the cut-points that differentiate normal from abnormal must be appropriate and should be specified in any report of a diagnostic test. The value chosen for a cutoff point


FIGURE 3–1 Defining a normal range and diagnostic testing. The top panel shows the Gaussian (normal) distribution of test values in a population of individuals. The middle panel illustrates two such curves that describe the findings in an ideal test. In this case, there is no overlap in the results between normal subjects and subjects with disease (ie, there are no false-positive results and no false-negative results). The bottom panel illustrates the results for a less-than-ideal test. Normal subjects with test values above the given threshold have abnormal results (ie, false-positive results), whereas some subjects with disease have test values below that threshold (ie, normal or false-negative results).

also affects the sensitivity and specificity. To assist the clinician in assessing a report on a diagnostic test, a series of questions has been proposed (Table 3–1).

The overnight dexamethasone suppression test is commonly used as a screening test in the diagnosis of Cushing syndrome, and its use illustrates some of the issues in diagnostic testing. As shown

in Figure 3–3, combining the results of a number of studies indicates a sensitivity of 98.1% and specificity of 98.9%. However, the individual studies varied, with sensitivities ranging from 83% to 100% and specificities from 77% to 100%. Moreover, the studies used different cortisol assays, doses of dexamethasone, and criteria for a positive test. Caution must be exercised in drawing conclusions from the combining of such data. In order to apply the sensitivity and specificity of a test derived from one study sample to a different population, the test cannot deviate from methods used (eg, dose of dexamethasone, type of cortisol assay, and timing of dexamethasone administration) when the optimal cutoff was determined, and the sample studied must be similar to the new population to be tested. To meet this latter prerequisite, the sample studied must account for variability of diseased individuals. This requires that subjects with disease be defined using the best available gold standard (independent of the test in question) and include a broad enough cross-section of those with disease (eg, mild vs severe disease, different etiologies of disease, as well as age, sex, and race) to establish a reliable range of measurements. The characteristics of the reference sample of subjects without the disease are equally important. Although the 1-mg overnight dexamethasone suppression test is still believed to have excellent, albeit less than 100% sensitivity, it has serious problems with specificity, and false-positive results have been described with a variety of drugs as well as medical, surgical, and psychiatric conditions.

One additional method of reporting the performance of a test is diagnostic accuracy. This can also be derived from the 2 × 2 table. Diagnostic accuracy is defined as the ability of a test to identify correctly those with the disease and those without the disease:

$$\text{Diagnostic accuracy} = \frac{(TP + TN)}{(TP + TN + FP + FN)}$$

From Crapo's composite data on the 1-mg overnight dexamethasone suppression test, the diagnostic accuracy is calculated as 98.7%. In addition to the characteristics of the study subjects, the number of subjects included in the sample is also critical to assess the accuracy of the test. Each operating characteristic determined in a study should be accompanied by a **confidence interval (CI)**—a range of values calculated from sample size and standard error which expresses a degree of confidence (usually 90%, 95%, or 99%) that the unknown true sensitivity or specificity lies in that interval. CIs are a measure of the precision of an estimate. The range of a CI depends on two factors: (1) the number of observations; and (2) the spread in the data (commonly measured as a standard deviation). The fewer the number of observations, the larger the range of the CI, and the greater the standard deviation of the data, the larger the range of the CI.

In addition to the limitations on the operating characteristics based on the samples from which the data are derived, sensitivity and specificity are not independent of each other. They vary with the cutoff level chosen to represent positive and negative test results. In general, as sensitivity increases, specificity decreases and as specificity increases, sensitivity decreases. This phenomenon is depicted graphically in an ROC curve.

		Disease	
		+ Present	**− Present**
Test result	+	a True positive (TP)	b False positive (FP)
	−	c False negative (FN)	d True negative (TN)

Sensitivity = a/(a + c) = TP/(TP + FN)

Specificity = d/(b + d) = TN/(TN + FP)

Positive predictive value = a/(a + b) = (TP/TP + FP)

Negative predictive value = d/(c + d) = TN/(TN + FN)

Diagnostic accuracy = (a + d)/(a + b + c + d) = (TP+TN)/(TP + FP + TN + FN)

Pretest (prior) probability = (a + c)/(a + b + c + d) = (TP + FN)/(TP + FP + TN + FN)

Likelihood ratio for a positive test result (LR+):

    = [a/(a + c)]/[b/b(b + d)] = TP rate/FP rate = [TP/(TP + FN)/(FP/TN + FP)]

    = sensitivity/(1 − specificity)

Likelihood ratio for a negative test result (LR−):

    = [c/(a + c)]/[d/(b + d)] = FN rate/TN rate = [FN/(TP + FN)]/[TN + FP]

    = (1 − sensitivity)/specificity

FIGURE 3–2 This 2 × 2 table graphically depicts how tests can be performed in individuals with and without a disease.

ROC Curves

An ROC curve graphically illustrates the trade-off between the false-negative and false-positive rates for different cutoff points of a diagnostic test. In an ROC curve, the true-positive rate (sensitivity) is plotted on the vertical axis and the false-positive rate (1–specificity) is plotted on the horizontal axis for different cutoff points for the test. The dotted diagonal line in Figure 3–4 corresponds to a test that is positive or negative just by chance (ie, the true-positive rate equals the false-positive rate). Such a test provides no useful information. Ideally, a test would provide results that could be plotted on one point in the top left corner—100%

true-positive rate and 100% true-negative rate. The closer an ROC curve is to the upper left-hand corner of the graph, the more accurate it is, because the true-positive rate is 1 and the false-positive rate is 0. As the criterion for a positive test becomes more stringent, the point on the curve corresponding to sensitivity and specificity (point A) moves down and to the left (lower sensitivity, higher specificity); if less evidence is required for a positive test, the point on the curve corresponding to sensitivity and specificity (point B) moves up and to the right (higher sensitivity, lower specificity). Analysis of the area between the actual results and the straight line indicates how good the test is. The greater the area under the curve, the better the test.

Depending on the purpose of the test, the curves may be used to decide an optimal cutoff level for a single test. For example, with a screening test, high sensitivity is typically desired, and the trade-off is lower specificity. The cutoff point may also be chosen depending on health costs (morbidity and mortality associated with an error in diagnosis), financial costs, or need for maximal information (the operating position giving the greatest increase in posttest probability).

ROC curves may also be used to compare two or more tests by comparing the areas under the curves, which represent the inherent accuracy of each test. An example of the comparison of the performance of different tests for the diagnosis of pheochromocytoma is given in Figure 3–5. It is important to remember, however, that ROC curves are only as good as the operating characteristics from which they are generated.

Finally, determining cost-effective diagnostic strategies requires careful evaluation not only of a test in isolation, but also in the context of the other information available and the likelihood of disease. This is the essence of Bayesian models of decision-making.

TABLE 3–1 Guide for evaluating studies of test performance.

Question #1	Is the study population described well enough?
Question #2	Does the spectrum of illness in the study population differ from that of my patients (eg, spectrum bias)?
Question #3	Was a positive result on the index test a criterion for referral to have the gold standard test?
Question #4	Was there blinding of those who interpreted the index test and those who interpreted the gold standard test (eg, test review bias)?
Question #5	Was the gold standard test an adequate measure of the true state of the patient?

Data from Jaeschke R, Guyatt G, Sackett DL. Users' guide to the medical literature. III. How to use an article about a diagnostic test. A. Are the results of the study valid? *JAMA.* 1994;271:389-391; and Jaeschke R, Guyatt G, Sackett DL. Users' guide to the medical literature. III. How to use an article about a diagnostic test. B. What are the results and will they help me in caring for my patients? *JAMA.* 1994:271:703.

		Cushing syndrome	
		Present	Absent
1-mg overnight dexamethasone suppression	No suppression	151	5
	Suppression	3	461

Sensitivity = 151/(151 + 3) = 98.1%

Specificity = 461/(5 + 461) = 98.9%

A

		Cushing syndrome	
		Present	Absent
1-mg overnight dexamethasone suppression	No suppression	151	101
	Suppression	3	858

Specificity = 858/(101 + 858) = 89.5%

B

		Cushing syndrome	
		Present	Absent
1-mg overnight dexamethasone suppression	No suppression	151	96
	Suppression	3	397

Specificity = 397/(96 + 397) = 80.5%

C

FIGURE 3–3 Diagnosis of Cushing syndrome with the 1-mg overnight dexamethasone suppression test: test characteristics with normal controls (**Panel A**); all controls (**Panel B**); and "obese" and "other" controls (**Panel C**). These data show how the specificity of the test is affected by the types of control subjects. (Data from Crapo L. Cushing's syndrome: a review of diagnostic tests. *Metabolism*. 1979 Sep;28(9):955-977.)

In this model, the physician updates his or her belief in a hypothesis with each new item of information, with different weights given to the new information depending on its operating characteristics. Consideration must be given to the question of the value added by a test or procedure. This can be assessed with ROC curves and statistical models.

Predictive Values, Likelihood Ratios, and Diagnostic Accuracy

Sensitivity and specificity are important test characteristics, yet the clinician wants to know how to interpret a test result. Predictive values help in this regard. As shown in Figure 3–6, the **positive predictive value** is the proportion of patients with a positive test who actually have the disease. Similarly, the **negative predictive value** is the proportion of those with a negative test who do not have the disease. Because each of these values are calculated using results from both individuals with and without the disease in question, the prevalence of the disease has a great impact on the values. For any given sensitivity and specificity, the lower the prevalence

of disease (or the lower the pretest probability), the more false-positive results there are (see Figure 3–6).

The **likelihood ratio**, which is derived from sensitivity and specificity, is an expression of the odds that a sign, symptom, or test result is expected in a patient with a given disease as opposed to one without the disease. Two forms of the likelihood ratio exist, the likelihood ratio for a positive finding and the likelihood ratio for a negative finding. Calculations are shown in Figure 3–2. Likelihood ratios offer some advantages over sensitivity and specificity. They are the most useful in calculating posttest probabilities given prevalence (a probability) and likelihood ratios. A convenient nomogram for this has been published (Figure 3–7).

AN APPROACH TO DIAGNOSIS IN PRACTICE

In approaching a case, the clinician makes a series of inferences about the nature of a patient's condition and proceeds toward a working diagnosis along with some alternatives—generation of a
FIGURE 3–4 Receiver-operating characteristic (ROC) curve. In an ROC curve, the true-positive rate (sensitivity) is plotted on the vertical axis, and the false-positive rate (1 – specificity) is plotted on the horizontal axis for different cutoff points for the test. The dotted diagonal line corresponds to a test that is positive or negative just by chance (ie, the true-positive rate equals the false-positive rate). The closer an ROC curve is to the upper left-hand corner of the graph, the more accurate it is, because the true-positive rate is 1 and the false-positive rate is 0. As the criterion for a positive test becomes more stringent, the point on the curve corresponding to sensitivity and specificity (**point A**) moves down and to the left (lower sensitivity, higher specificity); if less evidence is required for a positive test, the point on the curve corresponding to sensitivity and specificity (**point B**) moves up and to the right (higher sensitivity, lower specificity). Analysis of the area between the actual results and the straight line indicates how good the test is. The greater the area under the curve, the better the test.

differential diagnosis. Although one could create a listing of all possible causes of the patient's complaint (ie, a possibilistic differential diagnosis), experienced clinicians generate a differential diagnosis that is a combination of probabilistic (ie, considering first those disorders that are more likely), prognostic (ie, considering first those disorders that are more serious if missed), and pragmatic (ie, considering first those disorders that are most responsive to treatment). The clinician then refines the diagnostic hypotheses, sometimes using clues from the history and physical examination and often with the use of laboratory or radiologic tests. In so doing, the clinician tries to reduce the inherent uncertainty so that the most appropriate course of treatment can be prescribed.

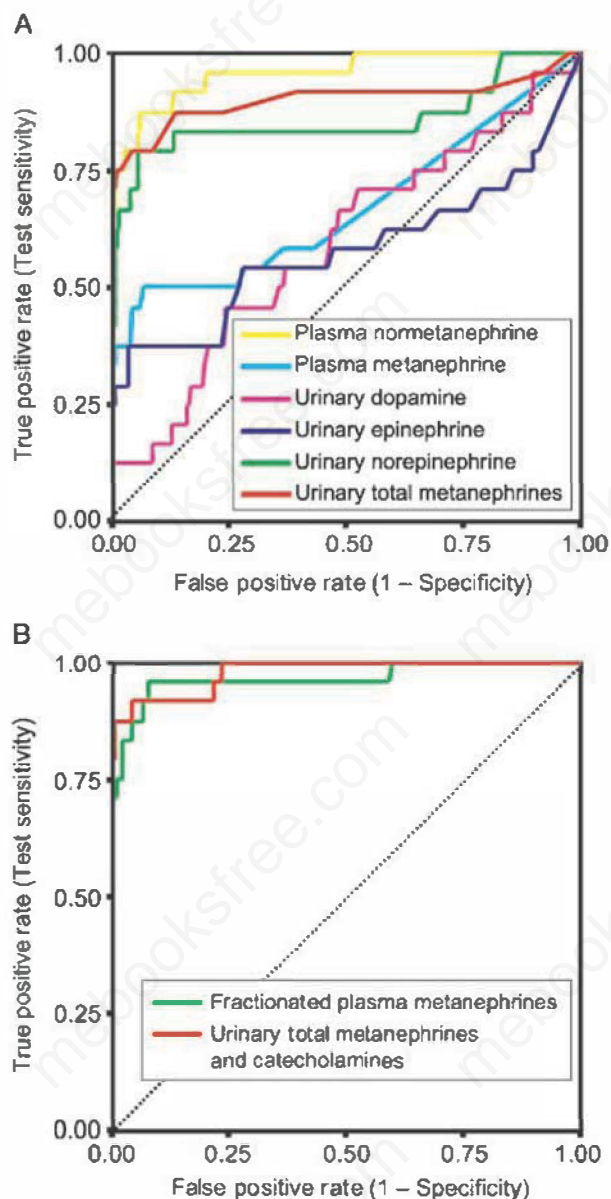
The first step in this process is to understand the concept of probability. A probability is an expression of likelihood and thus represents an opinion of the relative frequency with which an event is likely to occur. In the case of diagnosis, probability is a numerical expression of the clinician's uncertainty about a diagnosis; expressing a clinical opinion in subjective terms such as *likely* and *possible* is fraught with imprecision and misunderstanding. Certainty that a disease is present is assigned a probability of one,


FIGURE 3–5 Receiver-operating characteristic (ROC) curves for diagnostic tests for pheochromocytoma. The area under the curve from urinary total metanephrines and catecholamines and fractionated plasma metanephrines in Figure B exceeds that of other tests in Figure A indicating that they are more accurate overall.

Disease prevalence or pretest probability	0.1%	1%	10%	50%	90%
Positive predictive value	0.89%	8.33%	50.0%	90.0%	98.78%
Negative predictive value	99.99%	99.89%	98.78%	90%	50.0%

FIGURE 3–6 Positive and negative predictive values as a function of disease prevalence, assuming test sensitivity and specificity of 90% for each.

certainty that a disease is not present is assigned a probability of zero, and a clinician's opinion of the disease being present or absent usually falls somewhere in between. Of course, probabilities are derived from different data sources that vary in their reliability and application to a given patient, such as the clinician's experience (remembered cases), research studies, and population-based epidemiologic studies. Therefore, some degree of uncertainty is inherent in a given probability, and the confidence with which one can rely on a given probability depends to a large extent on the data underlying it.

The diagnostic approach to minimizing uncertainty requires four steps. First, the clinician starts with an estimate of probability based on initial clinical impressions. This starting point is dubbed the *pretest* or a priori probability and is a number between zero and one that expresses the likelihood of disease. For example, a clinician who sees a large population of patients with diabetes mellitus may think that a 55-year-old patient with polyuria, polydipsia, weight loss, and fatigue has a probability of 0.70 of having diabetes mellitus (ie, if there were 100 such individuals, 70 would have diabetes).

Second, the clinician determines the *threshold probability for treatment*. The treatment threshold probability is defined as the probability of disease at which one is indifferent between giving treatment and withholding treatment. Establishing a treatment threshold probability takes into account the costs (not just in the monetary sense) and benefits of treating or not treating.

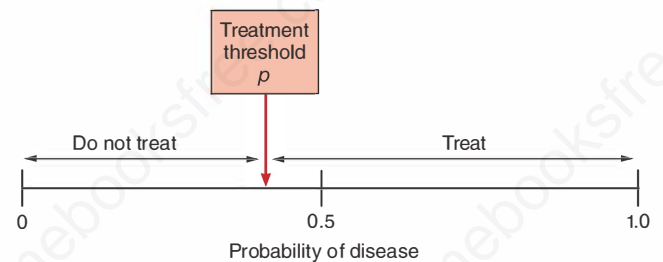
Because probability is predicated on the lack of certainty about the presence or absence of disease, it is inevitable that some patients who are not diseased receive treatment and others who are diseased do not receive treatment. Third, if the pretest probability is greater than the threshold probability, the clinician chooses to treat; if it is less than the threshold probability, the clinician opts not to treat. If the clinician is not comfortable enough about the presence or absence of disease, he or she may choose to order further tests with the objective of getting closer to certainty. The fourth step involves taking information gained from the test and using it to update the pretest probability. The updated, or *posttest*, probability can also serve as a new *pretest* probability for the next step in hypothesis testing (Figure 3–8).


FIGURE 3–8 Adjusting probabilities with new information and treatment thresholds. The top panel shows a pretest probability of disease of approximately 0.4. With the new information provided by a test, the probability rose to approximately 0.7. The middle panel shows the same pretest probability, but a negative test result reduced the probability of disease to approximately 0.15. The treatment threshold probability is the probability above which one would treat. The actual threshold value depends on the morbidity and mortality of disease and the adverse effects (morbidity and mortality) of treatment.

Treatment threshold probability depends on the effectiveness of treatment, including its adverse effects. In general, treatment threshold probability is generally low when treatment has a high benefit for diseased patients and/or a low risk of harm for non-diseased patients. Likewise, the treatment threshold probability is generally high when there is a high risk to nondiseased patients and/or a low benefit to diseased patients. For example, an endocrinologist evaluating an incidentally found pituitary microadenoma would need to be as certain as possible that the patient suffered from hormone hypersecretion before recommending surgical resection because of the high risk of harm to nondiseased patients relative to the benefit to diseased patients. The same principles apply to diagnostic testing. There is a *test-threshold* defined as the probability of disease at which one is indifferent between performing a test and not performing a test. Depending on the circumstances, one would treat without performing the test or not perform the test and ignore the issue entirely.

Tests can be combined in the hope that diagnostic accuracy is enhanced. Two tests can be performed in parallel (simultaneously) or in series (sequentially). When two tests are performed in parallel, a positive result in either test establishes the diagnosis; when two tests are performed in series, positive results in both tests are required to make the diagnosis. Thus, parallel testing increases sensitivity at the cost of specificity, whereas series testing increases specificity at the cost of sensitivity. For this approach to be better than one test alone, the second test has to provide information not provided by the first test. A common practice is to repeat the same test. This approach may be quite logical when the disorder is intermittently active (eg, intermittent Cushing syndrome) or when there is concern about the way the first test was performed. When tests are performed in series, the first test is usually the one with the higher sensitivity so that as many patients with the disease are discovered. False-positive results are then identified by a second test with higher specificity. Another approach to sequential testing uses as the first test the one with highest specificity so that fewer patients without the disease go on to further testing. This approach makes sense when the second test is associated with more morbidity. Adjusting cutpoints for the first test can make it 100% specific (at the cost of some sensitivity). This approach has been used frequently in tests related to Cushing syndrome. One caveat applies to the method of choosing the cutoff point. In addition to considering whether the patients without the disease are an appropriate control group, attention should be paid to sample size. Caution must be exercised when applying test characteristics derived from small samples.

CLINICAL EPIDEMIOLOGIC PRINCIPLES APPLIED TO TREATMENT DECISIONS

Critical to decision-making is the appropriate interpretation of the results of clinical trials and the impact of treatments on clinical events. The use of a 2 × 2 table can facilitate this process (Figure 3–9).

The **event rate (ER)** is the rate of occurrence of the outcome of interest. The **relative risk reduction (RRR)** is the proportional reduction in rates of bad outcomes between experimental and control participants in a trial, and it can be calculated as:

$$RRR = 1 - \text{relative risk} = 1 - (RRa/RRb)$$

RRR is usually reported accompanied by a 95% CI. **Absolute risk reduction (ARR)** is the absolute arithmetic difference in rates of poor outcomes between experimental and control participants in a trial and is usually accompanied by a 95% CI. Another way to think about this is to ask how many patients would have to be treated in order to prevent one negative outcome or achieve one additional favorable outcome. This is termed **number needed to treat (NNT)**, and it is calculated as 1/ARR and accompanied by a 95% CI. An example is provided (see Figure 3–9) from the results of a clinical trial. In the United Kingdom Prospective Diabetes Study (UKPDS-38), hypertensive patients with type 2 diabetes were randomized to tight versus less tight blood pressure control. The patients with tight blood pressure control had fewer diabetes-related complications and fewer deaths due to diabetes compared to the patients with less tight blood pressure control. Over a period of 8 years of treatment, 15.9% of patients in the less tight control group had died of diabetes complications compared with 10.9% in the tight control group. If intervention results in an adverse event, then an equivalent term to quantify that effect would be **number needed to harm (NNH)**, which would indicate that how many patients need to be treated to cause harm to one patient.

To apply these statistics in clinical decision-making to patients, it is necessary to calculate ARR, RRR, and NNT. The RRR of 32% indicates that approximately one-third of the expected deaths were prevented by tight control of blood pressure. However, although the RRR may be similar across different risk groups, the ARRs are not. ARRs become smaller when event rates are low, whereas RRR remains constant. Thus, RRR can be misleading. The lower the ER in the control group, the larger the difference between RRR and ARR. In other words, the benefits of treatment as reflected in ARR are usually greater in patients at higher risk of negative outcomes than in patients at lower risk of negative outcomes.

The RRR fails to discriminate absolute treatment effects that are clinically significant from those that are trivial. The NNT is 20, so that one would need to treat 20 patients for 8 years with tight blood pressure control to prevent one death from diabetes. NNT can be readily used to compare different treatments. In this case, RRR was 32% and ARR was 5.1%. If a different treatment with the same RRR of 32% has an ARR of 0.51%, the NNT would be 196, indicating that a much greater effort would be needed to achieve one additional favorable outcome. This might or might not be worth the effort, depending on a variety of factors. One method by which treatment thresholds can be determined is with the method of decision analysis.

		Outcome	
		Negative outcome	Positive outcome
Treatment group	Experimental	a	b
	Control	c	d

Relative risks

RRa—risk rate of the negative outcome occurring in the experimental group = a/(a + b)

RRb—risk rate of the negative outcome occurring in the control group = c/(c + d)

RR—the relative risk of the negative outcome occurring in experimental treatment compared to control treatment = RRa/RRb = {a/(a + b)}/{c/(c + d)}

Relative risk reduction (RRR) = (1 − RR) X 100%

Absolute risk reduction (ARR) = RRb − RRa

Number needed to treat (NNT) = 1/ARR

EXAMPLE:

Figure 2 X 2 Table for UKPDS Trial of Tight Control of Blood Pressure in Patients with Diabetes

		Outcome—Deaths from diabetes	
		Negative outcome —Death	Positive outcome —Alive
Treatment group	Experimental (n = 758)	82	676
	Control (n = 390)	62	328

RRa—10.8%
RRb—15.9%
RR—0.68
RRR—32%
ARR—5.1%
NNT—20

FIGURE 3–9 A 2 × 2 table for treatment groups and outcomes.

DECISION ANALYSIS

Decision analysis is a mathematical tool designed to facilitate complex clinical decisions in which many variables must be considered simultaneously. This analytical procedure selects among available diagnostic or therapeutic options based on the probability and predetermined value (utility) of all possible outcomes of those options. Decision analysis provides a systematic framework for organizing all data relevant to the decision so that relevant uncertainties are less likely to be overlooked. Performing a decision analysis requires clear definition of the relationship between possible courses of action and their associated outcomes and assignment of numerical values to various courses of action. In so doing, decision analysis simplifies comparisons among different strategies.

There is substantial variation in duration and severity of disease between individuals. Choosing a treatment option in the setting of unpredictable effects is a difficult problem, and expected value decision-making is a useful tool. When individual outcomes are uncertain, expected value is the result that is expected *on average*. In preparing to perform a decision analysis, one first must define the problem with a clear statement of the strategies to be examined. Two or more strategies may be included. Clinical decisions have effects over different time frames. An important step in defining a decision problem is to decide the time horizon for outcomes to be evaluated. For example, if strategies for diabetes treatment are to be compared, a period of weeks to months may be appropriate for evaluating the risk of hypoglycemic episode. However, this relatively short time horizon would not be appropriate when the study outcome is diabetic retinopathy, where a time horizon of years would be a better choice. After choosing the problem and a single time horizon, carrying out a formal analysis typically involves six general steps:

1. Construction of a decision tree that maps out all the possibilities
2. Determination and assignment of probabilities
3. Assignment of utilities to each potential outcome

4. Determination of the expected utility
5. Choosing the course of action with the highest expected utility
6. Evaluation of the sensitivity of the chosen course of action to changes in probabilities and utilities

In a *decision tree*, the term decision alternative refers to one of the potential strategies to be analyzed. Each alternative should be listed. Figure 3–10 shows a sample decision tree that outlines strategies of medical versus surgical treatment for disease. The decision itself is represented by a box called a decision node. All of the possible outcomes for each decision alternative are listed. An event that has outcomes under the control of chance is denoted by a chance node. The symbol for a chance node is a circle. The series of events leading to the clinical outcomes is represented by a series of chance nodes and decision nodes. The decision tree is usually written from left to right, with the initial decision node on the far left and the final outcomes on the far right. A final outcome is represented by a terminal node, the symbol for which is a triangle. There may be any number of outcomes at a chance node. The listed outcomes should include all possible outcomes, and they must not overlap. In addition to this assumption of

mutual exclusivity, structuring a tree in this fashion assumes that the probability of occurrence of one event does not influence the probability of occurrence of another event(s). The decision tree structure should be as similar as possible for all strategies, because differences may lead to a structural bias in the analysis.

The decision tree described earlier is relatively simple, and this approach cannot readily represent complex, dynamic clinical situations with recurring events. More elaborate models, such as Markov models, can be used to represent the passage through multiple health states. Patients may transition from one health state to another with some probability within a specified time period or model cycle. Like each terminal node in a static decision tree, each health state in the Markov model is associated with a specific clinical measure, utility, or cost. A key assumption of the Markov model is that the future is determined only by the individual's present health state; events prior to that health state or how long it took to arrive there do not affect the individual's future, a simplifying assumption that may not hold true for some health problems.

One strength of the decision analysis process is that it may be used for a variety of outcome measures. The outcome measure of interest determines the information needed for analysis. For example, one may use clinical measures such as survival following total thyroidectomy for differentiated thyroid cancer, preservation of vision after laser photocoagulation, or meeting a target level for glycosylated hemoglobin. Economic measures provide measures of cost and resource use. When cost measures are included, it is important to consider whose perspective is represented; analyses may reflect the viewpoint of society as a whole, payers, or patients.

A detailed analysis of costs may be used for *cost-effectiveness analysis or cost–utility analysis*. Utility measures reflect outcome preferences. For an individual, utilities represent quality of life preferences. They are quantitative values used to summarize multiple dimensions, which may be conflicting. For example, decision-makers frequently must choose among strategies that have differing effects on length of life and quality of life and involving trade-offs between the two. Utilities are traditionally scored on a scale from 0 to 1. The ideal situation, often perfect health, is scored as a 1. The worst situation, death, is scored as a 0, and this assumes that there are no utilities worse than death. Intermediate states are assigned values between 0 and 1. For example, living with diabetes mellitus may receive a score of 0.80—less than perfect, but preferable to death. Among the assumptions underlying this approach are: stability of estimates of utilities, that is, the estimates obtained prior to experiencing an event will not change after the event has been experienced; and the it-does-not-matter-how-you-get-there assumption (ie, death or other outcomes have the same utility regardless of the route a patient takes in getting there).

There are different ways to obtain utility values for different health states. One relatively simple method is the visual analog scale, in which a subject is asked to rate a given health state on a scale from 0 to 100. There also are more specific ways of determining utility. The standard gamble approach was developed by von Neumann and Morgenstern as a method for assessing utility.

FIGURE 3–10 A decision tree with probabilities and utilities. This sample decision tree outlines two strategies for a hypothetical patient with an adrenal mass—observation versus surgery. The decision node (open square) represents the decision itself. All of the possible outcomes for each decision alternative are listed emanating from an open circle or chance node. The events are governed by chance. The series of events leading to the clinical outcomes is represented by a series of chance nodes and decision nodes. Terminal nodes (triangles) denote the outcomes. Probabilities and utilities are listed. These are derived from the literature or determined via utility elicitation methods. In this example, if observation is chosen, one lives with the anxiety of uncertainty about the nature of the mass, which has a utility of 0.99 and would occur 95% of the time, while the health state of long-term consequences which occurs 5% of the time has a utility of 0.6. Similarly, surgery is curative 99% of the time, but has a 1% mortality rate. Cure, the most preferred outcome has a utility of 1 while death has a utility of 0. The predicted outcome of observation is $(0.99 \times 0.95) + (0.6 \times 0.05)$ or 0.9705 compared to $(1 \times 0.99) + (0 \times 0.01)$ or 0.99 for surgery. This indicates that on the *average*, surgery is a better choice in this particular case. However, if the utilities were different or the probabilities of the outcomes were different, the choice might also be different.

One advantage of this method is that it incorporates the participant's attitudes about risk taking, because the process involves consideration of a hypothetical gamble. For example, consider a 70-year-old individual with heart failure, diabetes, and chronic renal failure who is found to have a 4-cm adrenal mass on a CT scan performed for unrelated reasons. There is no indication of hormonal production by the mass, but knowing about this mass causes anxiety because it could be malignant. This concern could be addressed by surgical removal of the mass, but there is a risk of surgical complications. The individual is asked whether s/he would rather live with the mass (and the anxiety) or gamble on surgery that would eliminate the mass (curative), but has a 10% mortality rate. If the patient prefers to live with the mass, then ask would s/he prefer to live with the mass or gamble on curative surgery that has a 0.1% mortality rate. Assume the individual chooses surgery. This iterative process continues varying the probabilities in the gamble until the two options (living with anxiety vs taking a risk of curative surgery are equally desirable, that is, the respondent is indifferent between the gamble and living with anxiety). We make the assumption that the utility of perfect health is 1 and death is 0. For example, if this point were a surgical risk of 1%, the utility of living with anxiety about the adrenal mass is 0.99 and the disutility, defined as 1-utility would be 0.01. Utilities of other health states can be determined in a similar fashion. The time trade-off method is another way of determining utility. The utility may be described as a number between 0 and 1. For example, a subject may consider 10 years with pain from diabetic neuropathy equivalent to 5 years in perfect health. The utility of diabetic neuropathy would be 0.5. Alternatively, the utility may be expressed in quality-adjusted life years (QALYs). To determine the number of QALYs associated with an outcome, the time horizon for the outcome state is specified. Often, this is a patient's life expectancy in a particular outcome state. The number of years in full health that the subject sees as equivalent to the specified time with that outcome is the corresponding number of QALYs.

Determine the Probability of Each Chance Event

Once the decision tree structure is formed, the probability of each chance event may be determined. In general, this is best performed by taking a systematic review of published, peer-reviewed literature. However, this approach assumes that probabilities derived from a period in the past accurately reflect the probabilities in the future. Moreover, it assumes that the probabilities derived from other settings apply to the one in question. However, all these probabilities must reflect actual practice. For example, if decision analysis is being used to determine the best strategy for specific individual patients, the probabilities must be those of the site when the care is to be delivered. At times, not all of the information needed for the decision tree is available. This frequently occurs during analysis of a relatively new practice. If possible, primary data may be collected or secondary data may be analyzed. Expert opinion may be used in the absence of relevant data. At a given chance node, the sum of probabilities equals one.

Deciding on a Strategy: Averaging Out and Folding Back the Tree

The goal of decision analysis is to identify the strategy that leads to the most favorable expected outcome. To calculate the expected outcome, one starts at the outcome measures (typically the far right). Each group of branches, which start at a single chance node, is reduced to a single numerical value by multiplying each outcome utility by the probability associated with that outcome and adding all of the values. This is the process of folding back the decision tree (see Figure 3–10). This process is repeated until there is a single numerical value for each strategy at the initial decision node. At this point, the expected outcome for each strategy has been calculated. The strategy with the more favorable outcome is the preferred strategy.

Discounting Future Events

A greater value is placed on current events than future events. It is better to pay $100 in 10 years rather than pay $100 now. Similarly, if one is to have a disease, it is preferable to have a disease in the future than to have it today. The value of a future event then depends on how far in the future it occurs. Discounting refers to calculating the present value of an outcome that occurs in the future. The discount rate is the annual rate at which costs are discounted, which is usually the rate of interest that money would bring if it were invested.

Sensitivity Analysis

The initial analysis, or base case analysis, uses the best estimates for each parameter of the model. However, these estimates may be off the mark. The purpose of sensitivity analysis is to determine which estimates have the greatest influence on the model, that is, test the stability or robustness of a conclusion over a range of structural assumptions, value judgments, and estimates of probability. A plausible range of values is determined for each parameter of the model. This process determines which of the parameters drive the model's results. Parameters can be tested one at a time (one-way sensitivity analysis), two at a time (two-way sensitivity analysis), or even more (multi-way sensitivity analysis), though the latter become more difficult to interpret as the number of parameters tested is increased.

Cost-Effectiveness Analysis Using Decision Analysis

Cost-effectiveness analysis is the use of decision analysis to compare strategies in terms of their cost per unit of output. Output is an outcome such as years of life, utility, or cases of disease prevented. Cost-effectiveness ratios are interpreted by comparing them to ratios for other strategies. An incremental cost-effectiveness ratio indicates how much additional money needs to be spent for a better, but more expensive strategy to generate one additional unit of outcome.

Of practical importance, there usually is a limit to the amount of money a policy-maker is willing to spend to gain one QALY;

TABLE 3–2 Users' guide to decision analyses.

I. Are the results of the study valid?
   Were all important strategies and outcomes included?
   Was an explicit and sensible process used to identify, select, and combine the evidence into probabilities?
   Were the utilities obtained in an explicit and sensible way from credible sources?
   Was the potential impact of any uncertainty in the evidence determined?

II. What are the results?
   In the baseline analysis, does one strategy result in a clinically important gain for patients? If not, is the result a "toss-up"?
   How strong is the evidence used in the analysis?
   Could the uncertainty in the evidence change the result?

III. Will the results help me in caring for my patients?
   Do the probability estimates fit my patients' clinical features?
   Do the utilities reflect how my patients would value the outcomes of the decision?

Data from Richardson WS, Detsky AS for the Evidence-Based Medicine Working Group; based on the *Users' Guides to Evidence-Based Medicine* and reproduced with permission from *JAMA*. 1995 Apr 26;273:1292-1295 and Richardson WS, Detsky AS: Users' guides to the medical literature. VII. How to use a clinical decision analysis. B. What are the results and will they help me in caring for my patients? Evidence Based Medicine Working Group, *JAMA*. 1995 May 24-31;273(20):1610-1613.

this is termed the willingness-to-pay threshold. Cost–utility analysis is a specific type of cost-effectiveness analysis that uses QALYs (or other measures of utility) as the effectiveness end-point. By convention, cost–utility analyses are often called cost-effectiveness analyses. However, not all cost-effectiveness studies use the cost–utility methodology. Because they use QALYs as an end-point, cost–utility analyses generate information that may be compared across disease states. It is important to note that although they are useful in providing a common metric among outcomes, a number of stringent assumptions must be made to compare cost-effectiveness analyses. Principles for assessing decision analysis have been developed by the EBM working group and are shown in Table 3–2. Representative decision analyses related to endocrine disorders are shown in Table 3–3.

OTHER ASPECTS OF CLINICAL EPIDEMIOLOGY

The methods of clinical epidemiology have been applied to risk assessment, prognostication, the assessment of studies of different designs, and many other issues in clinical medicine. Readers are referred to standard texts.

EVIDENCE-BASED ENDOCRINOLOGY

The definition of EBM has evolved over time. A 2005 definition states that EBM requires the integration of the best research evidence with clinical expertize and patient's unique values and circumstances. The best research evidence refers to valid and clinically relevant research, often from the basic sciences of medicine, but especially from patient-centered clinical research. Clinical expertize refers to the ability to use physicians' clinical skills and past experience to rapidly identify each patient's unique health state and diagnosis, their individual risks and benefits of potential interventions, and their personal circumstances and expectations. Patient values consist of the unique preferences, concerns, and expectations each patient brings to a clinical encounter that must be integrated into clinical decisions if they are to serve the patient. Patient circumstances refer to the patient's individual clinical state and the clinical setting.

The five steps of EBM as defined in 1997 are discussed later. Entire textbooks are devoted to the principles of EBM. In this chapter, we will briefly review these five steps and focus on how EBM views evidence and review some of the limitations.

Step One: Translation of the Clinical Problem into Answerable Questions

One of the fundamental skills required for practicing EBM is the asking of well-built clinical questions. To benefit patients and clinicians, such questions need to be both directly relevant to patients' problems and phrased in ways that direct a literature search to relevant and precise answers. In practice, well-built clinical questions usually contain four elements: patient, intervention, comparison, and outcome. The patient refers to the individual to whom the evidence will be applied (eg, a hypertensive patient with diabetes). (The evidence-based approach can also be applied to a group to inform policy.) The intervention is the diagnostic test or therapy being considered for application to the particular patient (or group) (eg, tight control of blood pressure). The comparison is that intervention to which a new intervention being considered is to be compared (eg, less tight control of blood pressure). The outcome is the end-point of interest to the physician or patient (eg, stroke, myocardial infarction, or death from diabetes). Background questions relate to general information or basic facts about a disease, and this information can usually be found in reliable textbooks, whether published in book form or on-line. However, more patient-specific clinical questions, especially those that require the most up-to-date information about diagnosis, prognosis, or treatment, have been termed foreground questions and require a different approach to find relevant evidence.

Step Two: Finding the Best Evidence

The finding of best research evidence from the medical literature is a critical feature of the EBM approach and is an iterative process that involves medical informatics. Given the enormous breadth and depth of the medical literature, with more than two million articles published each year in about 20,000 biomedical journals (with more being established each year), efficient strategies must be used to take advantage of the best original journal articles, reviews and synopses of primary studies, and practice guidelines, along with textbooks, both traditional and innovative. Among the useful sources of information are PubMed, which allows sophisticated search strategies of the MEDLINE database. A variety of tools have been developed to facilitate this process. However, these are beyond the scope of this chapter, and readers are referred to references on the subject. Certain journals are specifically devoted

TABLE 3-3 Representative decision analyses in endocrinology.

Study	Clinical Problem and Strategies	Time Horizon	Outcome Measures	Results
Diabetes				
DCCT	Conventional vs intensive insulin therapy in approximately 120,000 persons with IDDM in the United States who meet DCCT inclusion criteria	Lifetime	Years free from diabetic complications Cost per life-year	Intensive insulin therapy results in a gain of 920,000 y of sight, 691,000 y free from ESRD, 678,000 y free from lower extremity amputation, and 611,000 y of life at a cost of $4 billion. Cost per life-year gained is $28,661.
Hoerger	Screening for type 2 DM in all people vs only screening those with hypertension	Lifetime	Cost per QALY	Screening in people with hypertension is more cost-effective. Targeted screening for people age 55-75 is most cost-effective.
Gillies	Different strategies for screening and prevention of type 2 DM in adults	Lifetime	Cost per QALY	Screening for type 2 DM and impaired glucose tolerance, with appropriate intervention for those with impaired glucose tolerance, in an above average risk population aged 45 seems to be cost-effective.
Golan	To preserve kidney function in patients with DM type 2, strategies of treating all patients with ACE inhibitors vs screening for microalbuminuria vs screening for gross proteinuria	Lifetime	Cost per QALY	Screening for gross proteinuria has the highest cost and lowest benefit. Compared with microalbuminuria, treating all patients with an ACE-inhibitor was beneficial with an IC-ER of $7500 per QALY gained.
Gaede	Intensified vs conventional multifactorial intervention in type 2 DM	Lifetime	Cost per QALY	From a health-care perspective in Denmark, intensive therapy was more cost-effective than conventional treatment. Assuming that persons in both arms were treated in a primary care setting, intensive therapy was both cost- and life-saving.
ACCORD	Intensive vs standard glycemic control in older patients with type 2 DM	Lifetime	Survival, adverse cardiovascular events	Intensive glycemic control did not help older patients with type 2 DM who had the disease for longer duration and had higher risk for cardiovascular disease. In fact it may cause harm to these individuals
Fried	To preserve kidney function in patient with type 2 DM by combination treatment of angiotensin converting enzyme inhibitor and angiotensin II receptor blocker	Lifetime	Slowing progression of chronic kidney disease	Combination therapy was associated with increased risk of adverse effects with no clear benefit.
Thyroid				
Danese	In asymptomatic adults, screening for mild thyroid failure every 5 y starting at age 35 vs no screening	Lifetime	Cost per QALY	Screening was cost-effective with a cost per QALY gained of $9223 for women and $22,595 for men.
Vidal-Trécan	Four strategies to treat solitary toxic thyroid adenoma in a 40-y-old woman: (A) Primary radioactive iodine (B) Primary surgery after euthyroidism achieved by ATDs (C) ATDs followed by surgery or (D) ATDs followed by radioactive iodine C and D were used if severe reaction to ATDs occurred	Lifetime	Cost per QALY	Surgery was the most effective and least costly strategy. Primary radioactive iodine was more effective if surgical mortality exceeded 0.6%.
Nasuti	Evaluation of FNA by a cytopathologist with on-site processing vs standard processing at the University of Pennsylvania Medical Center	Short term	Cost	By avoiding nondiagnostic specimens, an estimated cost savings of $404,525 per year may be achieved with on-site FNA review.
McCartney	Analysis of different thyroid nodule biopsy guideline criteria	Short term	Utility (expected value)	As a general approach to 10-14 mm thyroid nodules, routine FNA appears to be the least desirable compared with observation alone or FNA of nodules with ultrasonographic risk factors.
Wang	Cost effectiveness analysis of papillary thyroid cancer surveillance after total thyroidectomy	3 y	Cost of surveillance for each recurrence	Cost to detect each recurrence of papillary thyroid cancer in a low risk patient was more than 6 and 7 times greater than the cost for intermediate and high risk patients. It was $147,819, $22,434 and $20,680 for low, intermediate and high risk cancer respectively.

(Continued)

TABLE 3-3 Representative decision analyses in endocrinology. (*Continued*)

Study	Clinical Problem and Strategies	Time Horizon	Outcome Measures	Results
Other				
King	Four strategies to manage inciden-tal pituitary microadenoma in an asymptomatic patient: (1) Expectant management (2) PRL screening (3) Screening for PRL, insulin-like growth factor I, and (4) MRI follow-up	Lifetime	Cost per QALY	PRL test may be the most cost-effective strategy. Compared to expectant management, the IC-ER for PRL was $1428. The IC-ER for the extended screening panel was $69,495. MRI follow-up was less effective and more expensive.
Sawka	Three strategies to evaluate pheo-chromocytoma in patients with refractory hypertension, suspi-cious symptoms, adrenal mass, or history of pheochromocytoma: (A) Fractionated plasma metaneph-rines with imaging if abnormal (B) 24-h urinary metanephrines or catecholamines with imaging if abnormal (C) Plasma metanephrines if mod-estly elevated, urine studies to decide on imaging	Short term	Cost per pheochro-mocytoma detected	Strategy C is least costly and has reasonable sensitivity in patients with moderate pretest probability for pheochromocytoma.
Col	For menopausal symptom relief in healthy, white, 50-y-old women with intact uteri, use of hormone therapy vs no hormone therapy	2 y	Survival QALE	Hormone therapy is associated with lower survival but gains in QALE. Benefits depend on severity of menopausal symp-toms and CVD risk.
Smith	For 60-y-old men with erectile dys-function, sildenafil vs no drug therapy	Lifetime	Cost per QALY gained	From the societal perspective, cost per QALY gained with sildenafil is less than $50,000 if treatment-related morbid-ity is less than 0.55% per year, treatment success rate is greater than 40.2%, or cost of sildenafil is less than $244 per month.
Ollendorf	Comparing effectiveness and value of various treatment options for obesity. Comparing four types of bariatric surgery (biliopancreatic diversion, laproscopic adjustable gastric banding, Roux-en-Y gastric bypass, vertical sleeve gastrec-tomy with conventional weight loss management	10 y	Cost per QALY gained	Among patients with BMI 30.0 to 34.9 the cost–effectiveness of bariatric surgery compared to conventional weight loss management was $40,000 to $60000 per QALY.

to critically appraised articles (eg, ACP Journal Club, BMJ Evidence-Based Medicine). It is important to remember, however, that the presence of the label *evidence based* does not ensure that the information meets the highest standards. Systematic reviews are another useful source for evidence. In addition to the professional journals, such reviews are available from both governmental agencies (eg, Agency for Healthcare Research and Quality) and nongovernmental agencies (eg, the Cochrane Collaboration). Standards have been developed for reporting systematic reviews: preferred reporting items for systematic reviews and meta-analyses (PRISMA). Among the issues addressed specifically is that of publication bias and its potential effects on the results. Publication bias reflects, among other things, the tendency to not publish studies with negative findings.

Step Three: Appraising the Evidence for Its Validity and Usefulness

Critical appraisal is the process of systematically examining research evidence to assess its validity, results, and relevance before using it to inform a decision. There are three basic questions to be addressed in evaluating any kind of research: (1) Is it valid? (2) Is it important? and (3) Is it applicable to my patient? This involves assessment of the study's methods in order to assess the internal validity of the conclusions. Once criteria for internal validity are satisfied, then the importance of the finding can be assessed. It is critical that statistical significance not be equated with clinical significance. Assuming the finding is important, it is necessary to consider the study's relevance to the patient (ie, the external validity of the study). A series of guides has been developed to help the clinician to critically appraise different types of studies. An example is shown in Table 3–4. Underlying this appraisal process is the EBM model of the hierarchy of evidence.

A. Hierarchies of evidence   Any empirical observation about the apparent relation between events constitutes evidence. This includes the thoughtful observations of an experienced clinician, the observations derived from physiologic experiments, and the results of large, randomized clinical trials. Methodological safeguards to protect against systematic error (bias) are inherent in experimental design. In this way, experiments differ from clinical observations. Different study designs lend themselves to different safeguards, and these safeguards vary in their efficacy both in theory and in practice.

The EBM approach uses a hierarchy of study designs based on their inherent safeguards. A hierarchy is shown in Table 3–5. In this hierarchy, randomized controlled trials (RCTs) are given the highest weight, followed by quasi-experimental studies (ie, no-RCTs), followed by other study designs, and finally opinions of authorities and unsystematic clinical observations. Evidence from the top of the hierarchy should have greater impact in clinical decision-making than observations from the lower levels. There is disagreement about what the hierarchy should be. Some have an N of 1 randomized trial (the equivalent of an RCT with one subject) at the top of the hierarchy, whereas others place meta-analyses of randomized trials at the top. However, the term *evidence* is

---

TABLE 3–4 Users' guides for an article about therapy.

I. Are the results of the study valid?
Primary Guides
Was the assignment of patients to treatments randomized?
Were all patients who entered the trial properly accounted for and attributed at its conclusion?
Was follow-up complete?
Were patients analyzed in the groups to which they were randomized?
Secondary Guides
Were patients, health workers, and study personnel "blind" to treatment?
Were the groups similar at the start of the trial?
Aside from the experimental intervention, were the groups treated equally?
II. What were the results?
How large was the treatment effect?
How precise was the estimate of the treatment effect?
III. Will the results help me in caring for my patients?
Can the results be applied to my patient care?
Were all clinically important outcomes considered?
Are the likely treatment benefits worth the potential harms and costs?

Data from Guyatt GH, Sackett D, Cook DJ, for the Evidence Based Medicine Working Group. How to use a clinical decision analysis. B. What are the results and will they help me in caring for my patients? Evidence Based Medicine Working Group, *JAMA.* 1995 May 24-31;273(20):1610-1613.

---

not synonymous with evidence from RCTs (or whatever study design occupies at the preferred level of the hierarchy). Rather, it is preferred to use that sort of evidence when it is available. Evidence from other sources is still evidence and may be more than sufficient. For example, the introduction of thyroid replacement therapy for hypothyroidism or insulin therapy for type 1 diabetes has never been subjected to RCTs.

While recognizing the central role of evaluating the quality of the evidence in decision-making, the U.S. Preventive Services Task Force (USPSTF) has developed a different approach to address some of the shortcomings of the EBM approach. The USPSTF adopted three major changes to the process. First, a rating of internal validity was added to the study criterion for judging individual studies. A well-designed cohort or case-control study could be more compelling than an inadequately powered or poorly

TABLE 3–5 A hierarchy of evidence.

1. Evidence obtained from at least one properly designed randomized controlled trial.
2a. Evidence obtained from well-designed controlled trials without randomization.
2b. Evidence obtained from well-designed cohort or case-control analytical studies, preferably from more than one center or research group.
2c. Evidence from comparisons between times or places with or without the intervention. Dramatic results in uncontrolled experiments could be included in this section.
3. Opinions of respected authorities, based on clinical experience, descriptive studies, or reports on expert committees.

conducted RCT. Second, evidence was explicitly assessed at three different levels—the level of the individual study, both in terms of internal and external validity; the body of evidence supporting a given linkage in the analytic framework; and, because of the focus of the USPSTF, the level of evidence for the entire preventive service. Third, the magnitude of effect was separated from the assessment of quality. Both benefit and harm are considered in assessing the magnitude of the effect(s). Overall, the USPSTF grades the quality of the overall evidence for a service on a three-point scale (good, fair, poor) and grades its recommendations according to one of five classifications (A, B, C, D, I) reflecting the strength of evidence and magnitude of net benefit (benefits minus harms) (Table 3–6). This approach of assessing both the quality of evidence and strength of recommendations has been expanded to include practice guidelines: grading of recommendations, assessment, development, and evaluation (GRADE) system. Although a discussion of practice guidelines is beyond the scope of this chapter, it is important to recognize that they vary widely in quality, strength of evidence, and bias. Before a practitioner bases a decision on a practice guideline, the basis of that guideline must be clear.

TABLE 3-6 The USPSTF grading system for recommendations reflecting the strength of evidence and magnitude of net benefit (benefits minus harms).

Grade	Definition	Suggestions for Practice
A	The USPSTF recommends the service. There is high certainty that the net benefit is substantial.	Offer or provide this service.
B	The USPSTF recommends the service. There is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial.	Offer or provide this service.
C	The USPSTF recommends selectively offering or providing this service to individual patients based on professional judgment and patient preferences. There is at least moderate certainty that the net benefit is small.	Offer or provide this service for selected patients depending on individual circumstances.
D	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.	Discourage the use of this service.
I Statement	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.	Read the clinical considerations section of USPSTF Recommendation Statement. If the service is offered, patients should understand the uncertainty about the balance of benefits and harms.
Levels of Certainty Regarding Net Benefit		
Level of Certainty[*]	Description	
High	The available evidence usually includes consistent results from well-designed, well-conducted studies in representative primary care populations. These studies assess the effects of the preventive service on health outcomes. This conclusion is therefore unlikely to be strongly affected by the results of future studies.	
Moderate	The available evidence is sufficient to determine the effects of the preventive service on health outcomes, but confidence in the estimate is constrained by such factors as: • The number, size, or quality of individual studies. • Inconsistency of findings across individual studies. • Limited generalizability of findings to routine primary care practice. • Lack of coherence in the chain of evidence. As more information becomes available, the magnitude or direction of the observed effect could change, and this change may be large enough to alter the conclusion.	
Low	The available evidence is insufficient to assess effects on health outcomes. Evidence is insufficient because of: • The limited number or size of studies. • Important flaws in study design or methods. • Inconsistency of findings across individual studies. • Gaps in the chain of evidence. • Findings not generalizable to routine primary care practice. • Lack of information on important health outcomes. More information may allow estimation of effects on health outcomes.	

[*]The USPSTF defines certainty as "likelihood that the USPSTF assessment of the net benefit of a preventive service is correct." The net benefit is defined as benefit minus harm of the preventive service as implemented in a general, primary care population. The USPSTF assigns a certainty level based on the nature of the overall evidence available to assess the net benefit of a preventive service.

B. Other evidence-related issues   Notwithstanding these improvements, there are four other major issues concerning the evidence. First, it is important to recognize that virtually all of this evidence is essentially quantitative in nature. Thus, the EBM definition of evidence is relatively narrow and excludes information important to clinicians; many qualitative factors are involved in clinical decision-making concerning individual patients. Second, there are problems in the evidence in terms of the quality and scope of the data (eg, the soft data that clinicians usually use); the scope of the topics (average patients, gray zones of practice, lack of RCTs); sources of authority, which however explicit, require judgment; and potential abuses (eg, key findings could be ignored). Third, there is the issue of applying results in populations (ie, average results) to individuals. Fourth, there is the dynamic nature of evidence.

Evidence to support practice of medicine is always evolving with ongoing research in medical field and in that sense evidence would be dynamic. Whenever there is a change in evidence regarding an intervention, the best practice of medicine should incorporate that evidence into how clinical intervention is carried out. At times, new evidence may refute prior evidence, requiring a reversal in practice. In this case, health-care provider would need to "de-adopt" or "de-implement" a previously carried out medical practice. A good example is Action to Control Cardiovascular Risk in Diabetes (ACCORD) study failed to demonstrate clear benefit in survival for older patients with type 2 diabetes who were treated to achieve intensive control of blood glucose. Subsequent to the results of this study, both health-care providers and patients have to reset the target for blood glucose control to a higher range or less intensive control of blood glucose in this patient population.

Steps Four and Five: Applying the Results in Practice and Evaluating Performance

Knowledge of the best available evidence of treatment is not enough to recommend a particular course of action. Underlying this issue is heterogeneity of treatment effects. **Treatment effect heterogeneity** is the term given to the phenomenon in which the same treatment produces different results in different patients. For the average effect observed in a clinical trial to occur with certainty in one patient, all patients in the trial must have had that average response. Yet average response may also reflect a large response in some and small or no response or even harm in others. Part of clinical decision-making involves addressing this phenomenon to individualize therapy in the most effective way. To do so, four major factors about the patient must be taken into account: (1) baseline probability of incurring a disease-related adverse event (risk without treatment or susceptibility/prognosis), (2) responsiveness to the treatment, (3) vulnerability to the adverse side-effects of the treatment, and (4) utilities for different outcomes. When lacking good data on a patient's individual level of risk, responsiveness, and vulnerability, the average treatment effect as reported in good clinical trials provides the most reasonable guide for decision-making. However, it is important that physicians evaluate the results in their own patients so that the course can be modified when necessary.

Developments That May Affect the EBM Approach

Two developments are beginning to have an impact on EBM: "Big Data" and "Personalized Medicine." The global storage capacity for data has increased greatly and continues to do so. There are now data sets so large that the usual approaches do not work very well. Predictive analytics, a burgeoning field can identify new correlations to spot trends in a wide variety of fields including medicine. In contrast to the EBM approach which emphasizes the explicit control of biases in data collection and analysis, the "big data" approach generally involves the maxim "more data are better data." However, this approach can complement typical EBM methods. Another development is that of personalized medicine, also referred to as "precision medicine" in which patient genetic information (sometimes arrived at via a big data approach) is used to inform patient-specific treatment. This patient-specific information can complement evidence from the EBM hierarchy, which emphasizes what works on average. However, some things are unlikely to change. Practicing and perfecting the art of medicine demands recognition that uncertainty permeates all clinical decisions. How clinicians make decisions, whether diagnostic or therapeutic, by combining the art and the science is a complicated matter replete with unknowns. There is a variety of modes of clinical problem-solving ranging from automatic decisions in which a clinician makes a decision without consciously considering alternatives or even specific features of the problem to rational decision-making using simplified strategies to take into account probabilities and values of outcomes to formal decision analysis. The potential deficiencies of automatic decisions (nondecisions one might say) are obvious. Formal decision analyses, even if accepted as gold standards (which they are not), are beyond practical use for the vast majority of clinicians, so that we are left with simplified processes to combine likelihoods and values. However, even in striving to reduce uncertainty and coming up with the best course of action for the patient, it is critical to recognize that uncertainty will always be with us. In using a quantitative approach, we can only become more certain about the probability of the outcome. We cannot guarantee the desired outcome.

ACTH	Adrenocorticotropic hormone (corticotropin)		**IRMA**	Immunoradiometric assay
ADH	Antidiuretic hormone (vasopressin)		**KAL1**	Kallmann syndrome 1
CLIP	Corticotropin-like intermediate lobe peptide		**LH**	Luteinizing hormone
CRH	Corticotropin-releasing hormone		**β-LPH**	β-Lipotropin
CRHBP	Corticotropin-releasing hormone-binding protein		**Met-Enk**	Methionine-enkephalin
FGF8	Fibroblast growth factor 8		**MEN**	Multiple endocrine neoplasia
FGFR1	Fibroblast growth factor receptor 1		**MSH**	Melanocyte-stimulating hormone
FSH	Follicle-stimulating hormone		**PIH**	Prolactin-inhibiting hormone (dopamine)
GABA	Gamma-aminobutyric acid		**Pit-1**	Pituitary-specific positive transcription factor 1
GH	Growth hormone (somatotropin)		**POMC**	Pro-opiomelanocortin
GHBP	Growth hormone–binding protein		**PROK2**	Prokineticin 2
GHIH	Growth hormone–inhibiting hormone (somatostatin)		**PROKR2**	Prokineticin receptor 2
GHRH	Growth hormone–releasing hormone		**Prop-1**	Prophet of Pit-1
GHS-R	Growth hormone secretagogue receptor		**PRL**	Prolactin
GnRH	Gonadotropin-releasing hormone		*PTTG*	Pituitary tumor transforming gene
hCG	Human chorionic gonadotropin		**SHBG**	Sex hormone–binding globulin
hMG	Human menopausal gonadotropin		**SIADH**	Syndrome of inappropriate secretion of antidiuretic hormone
hPL	Human placental lactogen		**TRH**	Thyrotropin-releasing hormone
ICMA	Immunochemiluminescent assay		**TSH**	Thyroid-stimulating hormone (thyrotropin)
IGF	Insulin-like growth factor		**VIP**	Vasoactive intestinal peptide

The hypothalamus and pituitary gland form a unit that exerts control over the function of several endocrine glands—thyroid, adrenals, and gonads—as well as a wide range of physiologic activities. This unit is highly conserved across vertebrate species and constitutes a paradigm of neuroendocrinology—brain–endocrine interactions. The actions and interactions of the endocrine and nervous systems, whereby the nervous system regulates the endocrine system and endocrine activity modulates the activity of the central nervous system, constitute the major regulatory mechanisms for virtually all physiologic activities. These neuroendocrine interactions are also important in pathogenesis. This chapter reviews the normal functions of the pituitary gland, the neuroendocrine control mechanisms of the hypothalamus, and the disorders of those mechanisms.

Nerve cells and endocrine cells, which are both involved in cell-to-cell communication, share certain characteristic features—secretion of chemical messengers (neurotransmitters or hormones) and electrical activity. A single chemical messenger—peptide or amine—can be secreted by neurons as a neurotransmitter or neural hormone and by endocrine cells as a classic hormone. Examples of such multifunctional chemical messengers are shown in Table 4–1. The cell-to-cell communication may occur by four mechanisms:

TABLE 4–1 Neuroendocrine messengers: substances that function as neurotransmitters, neural hormones, and classic hormones.

	Neurotransmitter (Present in Nerve Endings)	Hormone Secreted by Neurons	Hormone Secreted by Endocrine Cells
Dopamine	+	+	+

Epinephrine	+		+
Somatostatin	+	+	+
Gonadotropin-releasing hormone (GnRH)	+	+	+
Thyrotropin-releasing hormone (TRH)	+	+	
Oxytocin	+	+	+
Vasopressin	+	+	+
Vasoactive intestinal peptide	+	+	
Cholecystokinin (CCK)	+		+
Glucagon	+		+
Enkephalins	+		+
Pro-opiomelanocortin derivatives	+		+
Other anterior pituitary hormones	+		+

(1) autocrine communication via messengers that diffuse in the interstitial fluid and act on the cells that secreted them, (2) neural communication via synaptic junctions, (3) paracrine communication via messengers that diffuse in the interstitial fluid to adjacent target cells (without entering the bloodstream), and (4) endocrine communication via circulating hormones (Figure 4–1). The two major mechanisms of neural regulation of endocrine function are direct innervation and neurosecretion (neural secretion of hormones). The adrenal medulla, kidney, parathyroid gland, and pancreatic islets are endocrine tissues that receive direct autonomic innervation (see Chapters 9, 10, and 11). An example of neurosecretory regulation is the hormonal secretion of certain hypothalamic nuclei into the portal hypophysial vessels, which regulate the hormone-secreting cells of the anterior lobe of the pituitary.

Another example of neurosecretory regulation is the posterior lobe of the pituitary gland, which is made up of the endings of neurons whose cell bodies reside in hypothalamic nuclei. These neurons secrete vasopressin and oxytocin into the general circulation.

Anatomy and Embryology

The anatomic relationships between the pituitary and the main nuclei of the hypothalamus are shown in Figure 4–2. The posterior lobe of the pituitary (neurohypophysis) is of neural origin, arising embryologically as an evagination of the ventral hypothalamus and the third ventricle. The neurohypophysis consists of the axons and nerve endings of neurons whose cell bodies reside in the supraoptic and paraventricular nuclei of the hypothalamus and

	Gap junctions	Synaptic	Paracrine	Endocrine
Message transmission	Directly from cell to cell	Across synaptic cleft	By diffusion in interstitial fluid	By circulating body fluids

supporting tissues. This hypothalamic-neurohypophysial nerve tract contains approximately 100,000 nerve fibers. Repeated swellings along the nerve fibers ranging in thickness from 1 to 50 μm constitute the nerve terminals.

The human fetal anterior pituitary anlage is initially recognizable at 4 to 5 weeks of gestation, and rapid cytologic differentiation leads to a mature hypothalamic-pituitary unit at 20 weeks. The anterior pituitary (adenohypophysis) originates from Rathke pouch, an ectodermal evagination of the oropharynx, and migrates to join the neurohypophysis. The portion of Rathke pouch in contact with the neurohypophysis develops less extensively and forms the intermediate lobe. This lobe remains intact in some species, but in humans its cells become interspersed with those of the anterior lobe and develop the capacity to synthesize and secrete pro-opiomelanocortin (POMC) and adrenocorticotropic hormone (ACTH). Remnants of Rathke pouch may persist at the boundary of the neurohypophysis, resulting in small colloid cysts. In addition, cells may persist in the lower portion of Rathke pouch beneath the sphenoid bone, the pharyngeal pituitary. These cells

have the potential to secrete hormones and have been reported to undergo adenomatous change.

The pituitary gland itself lies at the base of the skull in a portion of the sphenoid bone called the sella turcica (Turkish saddle). The anterior portion, the tuberculum sellae, is flanked by posterior projections of the sphenoid wings, the anterior clinoid processes. The dorsum sellae forms the posterior wall, and its upper corners project into the posterior clinoid processes. The gland is surrounded by dura, and the roof is formed by a reflection of the dura attached to the clinoid processes, the diaphragma sellae. The arachnoid membrane and, therefore, cerebrospinal fluid are prevented from entering the sella turcica by the diaphragma sellae. The pituitary stalk and its blood vessels pass through an opening in this diaphragm. The lateral walls of the gland are in direct apposition to the cavernous sinuses and separated from them by dural membranes. The optic chiasm lies 5 to 10 mm above the diaphragma sellae and anterior to the stalk (Figure 4–3).

The size of the pituitary gland, of which the anterior lobe constitutes two-thirds, varies considerably. It measures approximately
FIGURE 4–3 Anatomic relationships and blood supply of the pituitary gland. (Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism*. 3rd ed. New York: McGraw-Hill Education; 1995.)

15 × 10 × 6 mm and weighs 500 to 900 mg; it may double in size during pregnancy. The sella turcica tends to conform to the shape and size of the gland, and for that reason, there is considerable variability in its contour.

Blood Supply

The anterior pituitary is the most richly vascularized of all mammalian tissues, receiving 0.8 mL/g/min from a portal circulation connecting the median eminence of the hypothalamus and the anterior pituitary. Arterial blood is supplied from the internal carotid arteries via the superior, middle, and inferior hypophysial arteries. The superior hypophysial arteries form a capillary network in the median eminence of the hypothalamus that recombines in long portal veins draining down the pituitary stalk to the anterior lobe, where they break up into another capillary network and re-form into venous channels (see Figures 4–2 and 4–3). The pituitary stalk and the posterior pituitary are supplied directly from branches of the middle and inferior hypophysial arteries.

Venous drainage of the pituitary, the route through which anterior pituitary hormones reach the systemic circulation, is variable, but venous channels eventually drain via the cavernous sinus posteriorly into the superior and inferior petrosal sinuses to the jugular bulb and vein (Figure 4–4). The axons of the neurohypophysis terminate on capillaries that drain via the posterior lobe veins and the cavernous sinuses to the general circulation.

The hypophysial portal system of capillaries allows control of anterior pituitary function by the hypothalamic hypophysiotropic hormones secreted into the portal hypophysial vessels. This provides a short, direct connection to the anterior pituitary from the ventral hypothalamus and the median eminence (Figure 4–5). There may also be retrograde blood flow between the pituitary and hypothalamus, providing a possible means of direct feedback between pituitary hormones and their neuroendocrine control centers.

Pituitary Development and Histology

Anterior pituitary cells were originally classified as acidophils, basophils, and chromophobe cells based on staining with hematoxylin and eosin. Immunocytochemical and electron microscopic techniques now permit classification of cells by their specific secretory products: somatotrophs (growth hormone [GH]-secreting cells), lactotrophs (prolactin [PRL]-secreting cells), thyrotrophs (cells secreting thyroid-stimulating hormone [thyrotropin; TSH]), corticotrophs (cells-secreting ACTH [corticotropin] and related peptides), and gonadotrophs (luteinizing hormone [LH]– and follicle-stimulating hormone [FSH]–secreting cells). The development of the pituitary gland and the emergence of the distinct cell types from common primordial cells are controlled by a limited set of transcription factors, most notably Prop1 and Pit1 (Figure 4–6). The individual hormone-secreting
FIGURE 4–4   Venous drainage of the pituitary gland—the route by which adenohypophysial hormones reach the systemic circulation. (Reproduced with permission from Findling JW, Aron DC, Tyrrell JB, et al. FIGURE 4–5   Secretion of hypothalamic hormones. The hormones of the posterior lobe (PL) are released into the general circulation from the endings of supraoptic and paraventricular neurons, whereas hypophysiotropic hormones are secreted into the portal hypophysial circulation from the endings of arcuate and other hypothalamic neurons (AL, anterior lobe; ARC, arcuate and other nuclei; MB, mamillary bodies; OC, optic chiasm; PV, paraventricular nucleus; SO, supraoptic nucleus).

cells emerge in a specific order and from distinct lineages. Abnormalities of pituitary and lineage–specific transcription factors have been associated with the development of hypopituitarism. Although traditionally the pituitary has been conceptualized as a gland with distinct and highly specialized cells that respond to specific hypothalamic and peripheral hormones, it has become clear that local (ie, paracrine) factors also play a role in normal pituitary physiology.

A. Somatotrophs   The GH-secreting cells are acidophilic and usually located in the lateral portions of the anterior lobe. Granule size by electron microscopy is 150 to 600 nm in diameter. These cells account for about 50% of the adenohypophysial cells.

B. Lactotrophs   The PRL-secreting cell is a second but distinct acidophil-staining cell randomly distributed in the anterior pituitary. These cells account for 10% to 25% of anterior pituitary cells. Granule size averages approximately 550 nm on electron microscopy. There are two types of lactotrophs: sparsely granulated and densely granulated. These cells proliferate during pregnancy as a result of elevated estrogen levels and account for the twofold increase in gland size.

C. Thyrotrophs   These TSH-secreting cells, because of their glycoprotein product, are basophilic and also show a positive reaction with periodic acid-Schiff stain. Thyrotrophs are the least common pituitary cell type, making up less than 10% of adenohypophysial cells. The thyrotroph granules are small (50-100 nm), and these cells are usually located in the anteromedial
FIGURE 4–6 Temporal and spatial activation of pituitary transcription factors. In response to the BMP2-FGF8 ventral-dorsal gradient, pituitary cell lineages are determined by the activation or repression of each transcription factor. Solid arrows indicate the activation of expression, dotted arrows indicate an unknown role in the activation of expression, dashed arrows indicate an undefined role and dash-dot arrows indicate an action of an important factor in the maintenance of long-term cell function (Bmp2, bone morphogenic protein 2; Egr1, early growth response 1; ER, estrogen receptor; Fgf8, fibroblast growth factor 8; Gata2, GATA-binding protein 2; Hesx 1, HESX homeobox 1; Isl1, ISL LIM homeobox 1; Lhx3, LIM homeobox 3; Lhx4, LIM homeobox 4; Lif, leukemia inhibitory factor; Msx1, msh homeobox 1; NeuroD1, neurogenic differentiation 1; PIT1, POU class 1 homeobox 1; Pitx1, paired-like homeodomain 1; Pitx2, paired-like homeodomain 2; POMC, pro-opiomelanocortin; Prop1, prophet of Pit-1; RAR, retinoic acid receptor; SF1, steroidogenic factor 1; T3r, thyroid hormone nuclear receptor; TEF, thyrotrope embryonic factor; Tpit, T-box 19; Zn15, zinc finger protein Zn15). Pituitary development: a complex, temporal regulated process dependent on specific transcriptional factors. *J Endocrinol*. 2012 Nov;215(2):239-245.)

and anterolateral portions of the gland. During states of primary thyroid failure, the cells demonstrate marked hypertrophy, increasing overall gland size.

D. Corticotrophs   ACTH and its related peptides (see later) are secreted by basophilic cells that are embryologically of intermediate lobe origin and usually located in the anteromedial portion of the gland. Corticotrophs represent 15% to 20% of adenohypophysial cells. Electron microscopy shows that these secretory granules are about 360 nm in diameter. In states of glucocorticoid excess, corticotrophs undergo degranulation and a microtubular hyalinization known as Crooke hyaline degeneration (Figure 4–7).

E. Gonadotrophs   LH and FSH originate from basophil-staining cells, whose secretory granules are about 200 nm in diameter. These cells constitute 10% to 15% of anterior pituitary cells, and they are located throughout the entire anterior lobe. They become hypertrophied and cause the gland to enlarge during states of primary gonadal failure such as menopause, Klinefelter syndrome, and Turner syndrome.

TABLE 4–2 Major adenohypophysial hormones and their cellular sources.

Cellular Source and Histologic Staining	Main Hormone Products	Structure of Hormone	Main Functions
Somatotroph (acidophil)	GH; also known as STH or somatotropin	191 amino acids, 22-kDa protein, mainly nonglycosylated	Stimulates the production of IGF-1 (the mediator of the indirect actions of GH); also exerts direct actions on growth and metabolism
Lactotroph or mammotroph (acidophil)	PRL	198 amino acids, 23-kDa protein, mainly nonglycosylated (Note: most of the decidually produced PRL is glycosylated)	Stimulation of milk production (protein and lactose synthesis, water excretion, and sodium retention); inhibits gonadotropin; immunomodulator
Corticotroph (small cells with basophil granules with strong PAS positivity, indicating the presence of glycoproteins)	Derivatives of POMC, mainly ACTH and β-LPH	POMC: glycosylated polypeptide of 134 amino acid residues ACTH: simple peptide of 39 amino acid residues, 4.5 kDa β-LPH: simple peptide of 91 amino acid residues, 11.2 kDa	ACTH: stimulation of glucocorticoids and sex steroids in the zona fasciculata and zona reticularis of the adrenal cortex, inducing hyperplasia and hypertrophy of the adrenal cortex β-LPH: weak lipolytic and opioid actions
Thyrotroph (large cells with basophil granules with PAS positivity)	TSH	Glycoprotein hormone consisting of a shared α (89 amino acid) and a TSH-specific β (112 amino acid) subunit Total size: 28 kDa	Stimulation of all aspects of thyroid gland function: hormone synthesis, secretion, hyperplasia, hypertrophy, and vascularization
Gonadotroph (small cells with basophil granules with periodic acid-Schiff positivity)	LH: named after its effect in females; is identical to the ICSH (interstitial cell stimulating hormone) originally described in males	Glycoprotein hormone consisting of a shared α and an LH-specific β (115 amino acid) subunit Total size: 29 kDa	Females: stimulates steroid hormone synthesis in theca interna cells, lutein cells, and hilar cells; promotes luteinization and maintains corpus luteum Males: stimulates steroid hormone production in Leydig cells
	FSH	Glycoprotein hormone consisting of a shared α and an FSH-specific β (115 amino acid) subunit Total size: 29 kDa	Females: targets the granulosa cells to promote follicular development; stimulates aromatase expression and inhibin secretion Males: targets the Sertoli cells to promote spermatogenesis and to stimulate inhibin secretion

F. Other cell types   Some cells, usually chromophobes, contain secretory granules but do not exhibit immunocytochemical staining for the major known anterior pituitary hormones. These cells have been called null cells; they may give rise to (apparently) nonfunctioning adenomas. Some may represent undifferentiated primitive secretory cells, and others (eg, glia-like or folliculostellate cells) may produce one or more of the many paracrine factors that have been described in the pituitary. Mammosomatotrophs contain both GH and PRL; these bihormonal cells are most often seen in pituitary tumors. Human chorionic gonadotropin (hCG) is also secreted by the anterior pituitary gland, but its cell of origin and physiologic significance are uncertain. The six known major anterior pituitary hormones are listed in Table 4–2.

HYPOTHALAMIC HORMONES

The hypothalamic hormones can be divided into those secreted into hypophysial portal blood vessels and those secreted by the neurohypophysis directly into the general circulation. The hypothalamic nuclei, their neurohormones, and their main functions

are shown in Table 4–3. The structures of the eight major hypothalamic hormones are shown in Table 4–4.

Hypophysiotropic Hormones

The hypophysiotropic hormones that regulate the secretion of anterior pituitary hormones include growth hormone–releasing hormone (GHRH), somatostatin (growth hormone–inhibiting hormone [GHIH]), dopamine, thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), and gonadotropin-releasing hormone (GnRH). The location of the cell bodies of the hypophysiotropic hormone–secreting neurons is depicted in Figure 4–8. Most of the anterior pituitary hormones are controlled by stimulatory hormones, but GH and especially PRL are also regulated by inhibitory hormones. Some hypophysiotropic hormones are multifunctional. The hormones of the hypothalamus are secreted episodically and not continuously, and in some cases there is an underlying circadian rhythm.

A. GHRH   GHRH stimulates GH secretion by, and is trophic for, somatotrophs. GHRH-secreting neurons are located in the arcuate

TABLE 4–3 The hypothalamic nuclei and their main functions.

Nucleus	Location	Major Neurohormones or Functions
Supraoptic	Anterolateral, above the optic tract	ADH: osmoregulation, regulation of ECF volume Oxytocin: regulation of uterine contractions and milk ejection
Paraventricular	Dorsal anterior periventricular	Magnocellular paraventricular nucleus (PVN): ADH, oxytocin: same functions as above Parvocellular PVN TRH: regulation of thyroid function CRH: regulation of adrenocortical function, regulation of the sympathetic nervous system and adrenal medulla, regulation of appetite ADH: coexpressed with CRH, regulation of adrenocortical function VIP: prolactin-releasing factor (?)
Suprachiasmatic	Above the optic chiasm, anteroventral periventricular zone	Regulator of circadian rhythms and pineal function (zeitgeber [pacemaker]): VIP, ADH neurons project mainly to the PVN
Arcuate	Medial basal hypothalamus close to the third ventricle	GHRH: stimulation of growth hormone GnRH: regulation of pituitary gonadotropins (FSH and LH) Dopamine: functions as PIH Somatostatin: inhibition of GHRH release Regulation of appetite (neuropeptide Y, agouti-related transcript, α-MSH, cocaine- and amphetamine-related transcript)
Periventricular	Anteroventral	Somatostatin: inhibition of growth hormone secretion by direct pituitary action: most abundant SRIF location
Ventromedial	Ventromedial	GHRH (as above) Somatostatin: inhibition of GHRH release Functions as a satiety center
Dorsomedial	Dorsomedial	Focal point of information processing: receives input from ventromedial nucleus (VMN) and lateral hypothalamus and projects to the PVN
Lateral hypothalamus	Lateral hypothalamus	Functions as a hunger center (melanin-concentrating hormone, anorexins)
Preoptic area	Preoptic area	Main regulator of ovulation in rodents; only a few GnRH neurons in primates
Anterior hypothalamus	Anterior hypothalamus	Thermoregulation: cooling center Anteroventral third ventricular region: regulation of thirst
Posterior hypothalamus	Posterior hypothalamus	Thermoregulation: heating center

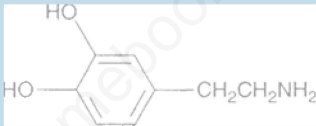
nuclei (see Figure 4–2), and axons terminate in the external layer of the median eminence. The major isoform of GHRH is 44 amino acids in length. It was isolated from a pancreatic tumor in a patient with clinical manifestations of GH excess (acromegaly) associated with somatotroph hyperplasia (see discussion later in the chapter). GHRH is synthesized from a larger precursor of 108 amino acids. Other secretory products derived from this precursor have also been found. Full biologic activity of these releasing factors appears to reside in the 1 to 29 amino acid sequence of the amino terminal portion of the molecule. Human GHRH is a member of a homologous family of peptides that includes secretin, glucagon, vasoactive intestinal peptide (VIP), and others. The half-life of GHRH is approximately 3 to 7 minutes.


B. Somatostatin   Somatostatin inhibits the secretion of GH and TSH. Somatostatin-secreting cells are located in the periventricular region immediately above the optic chiasm (see Figure 4–2) with nerve endings found diffusely in the external layer of the median eminence.

Somatostatin, a tetradecapeptide, has been found not only in the hypothalamus but also in the D cells of the pancreatic

islets, the gastrointestinal mucosa, and the C cells (parafollicular cells) of the thyroid. The somatostatin precursor has 116 amino acids. Processing of the carboxyl terminal region of preprosomatostatin results in the generation of the tetradecapeptide somatostatin 14 and an amino terminal extended form containing 28 amino acid residues (somatostatin 28). Somatostatin 14 is the major species in the hypothalamus, whereas somatostatin 28 is found in the gut. In addition to its profound inhibitory effect on GH secretion, somatostatin also has important inhibitory influences on many other hormones, including insulin, glucagon, gastrin, secretin, and VIP. This inhibitory hypothalamic peptide plays a role in the physiologic secretion of TSH by augmenting the direct inhibitory effect of thyroid hormone on the thyrotrophs; administration of antisomatostatin antibodies results in a rise in circulating TSH level. Somatostatin has a half-life of 2 to 3 minutes.

C. Dopamine   Dopamine, the primary PRL-inhibitory hormone, is found in the portal circulation and binds to dopamine receptors on lactotrophs. It has a short half-life, on the order of 1 to 2 minutes. The hypothalamic control of PRL secretion, unlike

TABLE 4–4 Hypothalamic hormones.

Hormone	Structure
Posterior pituitary hormones	
Arginine vasopressin	Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-Gly-NH$_2$ (disulfide bridge Cys–Cys)
Oxytocin	Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH$_2$ (disulfide bridge Cys–Cys)
Hypophysiotropic hormones	
Thyrotropin-releasing hormone (TRH)	(pyro)Glu-His-Pro-NH$_2$
Gonadotropin-releasing hormone (GnRH)	(pyro)Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH$_2$
Somatostatin[a] (growth hormone-inhibiting hormone [GHIH])	Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys (disulfide bridge Cys–Cys)
Growth hormone–releasing hormone (GHRH)	Tyr-Ala-Asp-Ala-Ile-Phe-Thr-Asn-Ser-Tyr-Arg-Lys-Val-Leu-Gly-Gln-Leu-Ser-Ala-Arg-Lys-Leu-Leu-Gln-Asp-Ile-Met-Ser-Arg-Gln-Gln-Gly-Glu-Ser-Asn-Gln-Glu-Arg-Gly-Ala-Arg-Ala-Arg-Leu-NH$_2$
Prolactin-inhibiting hormone (PIH, dopamine)	
Corticotropin-releasing hormone (CRH)	Ser-Gln-Glu-Pro-Pro-Ile-Ser-Leu-Asp-Leu-Thr-Phe-His-Leu-Leu-Arg-Glu-Val-Leu-Glu-Met-Thr-Lys-Ala-Asp-Gln-Leu-Ala-Gln-Gln-Ala-His-Ser-Asn-Arg-Lys-Leu-Leu-Asp-Ile-Ala-NH$_2$

[a]In addition to the tetradecapeptide shown here (somatostatin 14), an amino terminal–extended molecule (somatostatin 28), and a 12-amino-acid form (somatostatin 28 [1-12]) are found in most tissues.

that of the other pituitary hormones, is predominantly inhibitory. Thus, disruption of the hypothalamic-pituitary connection by stalk section, hypothalamic lesions, or pituitary autotransplantation increases PRL secretion. Dopamine-secreting neurons (tuberoinfundibular dopaminergic system) are located in the arcuate nuclei, and their axons terminate in the external layer of the median eminence, primarily in the same area as the GnRH endings (laterally) and to a lesser extent medially (see Figure 4–2). The neurotransmitter gamma-aminobutyric acid (GABA) and cholinergic pathways also appear to inhibit PRL release.

D. Prolactin-releasing factors   The best-studied factor with PRL-releasing activity is TRH (see discussion later), but there is little evidence for a physiologic role. PRL increase associated with sleep, during stress, and after nipple stimulation or suckling is not accompanied by an increase in TRH or TSH. Another hypothalamic peptide, VIP, stimulates PRL release in humans. Serotonergic pathways may also stimulate PRL secretion, as demonstrated by the increased PRL secretion after the administration of serotonin precursors and by the reduction of secretion following treatment with serotonin antagonists.

E. Thyrotropin-releasing hormone   TRH, a tripeptide, is the major hypothalamic factor regulating TSH secretion. Human TRH is synthesized from a large precursor of 242 amino acids that contains six copies of TRH. TRH-secreting neurons are located in the medial portions of the paraventricular nuclei (see Figure 4–2), and their axons terminate in the medial portion of the external layer of the median eminence. The half-life of TRH is approximately 6 minutes.

F. Corticotropin-releasing hormone   CRH, a 41-amino-acid peptide, stimulates the secretion of ACTH and other products of its precursor molecule, POMC. CRH is synthesized from a precursor of 196 amino acids. The half-life of CRH follows a biphasic pattern in plasma lasting approximately 6 to 10 minutes and 40 to 50 minutes. Both antidiuretic hormone (ADH) and angiotensin II potentiate CRH-mediated secretion of ACTH. In contrast, oxytocin inhibits CRH-mediated ACTH secretion. Opioids appear to suppress release of CRH. CRH-secreting neurons are found in the anterior portion of the paraventricular nuclei just lateral to the TRH-secreting neurons; their nerve endings are found in all parts of the external layer of the median eminence. CRH is also secreted from human placenta. The level of this hormone increases significantly during late pregnancy and delivery. In addition, a specific CRH-binding protein (CRHBP) has been described in both serum and in intracellular locations within a variety of cells. It is likely that CRHBPs modulate the actions and plasma half-life of CRH. Since the 1990s, three proteins homologous to CRH, termed urocortins, and two different receptors, have been identified. In addition to the role of CRH in the physiologic response to stress, this family of peptides appears to play a significant role in energy balance.

G. Gonadotropin-releasing hormone   The secretion of LH and FSH is controlled by a single stimulatory hypothalamic
FIGURE 4–8 Location of cell bodies of hypophysiotropic hormone-secreting neurons projected on a ventral view of the hypothalamus and pituitary of the rat (AL, anterior lobe; ARC, arcuate nucleus; BA, basilar artery; IC, internal carotid; IL, intermediate lobe; MC, middle cerebral; ME, median eminence; PC, posterior cerebral; Peri, periventricular nucleus; PL, posterior lobe; PVL and PVM, lateral and medial portions of the paraventricular nucleus; SO, supraoptic nucleus). Neuroendocrinology: The Hypothalamus as Part of a Larger System

The hypothalamus is involved in many nonendocrine functions such as regulation of body temperature, thirst, and food intake and is connected with many other parts of the nervous system. The brain itself is influenced by both direct and indirect hormonal effects. Steroid and thyroid hormones cross the blood–brain barrier and produce specific receptor-mediated actions (see Chapters 1, 7, and 9). Peptides in the general circulation, which do not cross the blood–brain barrier, elicit their effects indirectly (eg, insulin-mediated changes in blood–glucose concentration). In addition, communication between the general circulation and the brain may take place via the circumventricular organs, which are located outside the blood–brain barrier (see later). Moreover, hypothalamic hormones in extrahypothalamic brain function as neurotransmitters or neurohormones. They are also found in other tissues where they function as hormones (endocrine, paracrine, or autocrine). For example, somatostatin-containing neurons are widely distributed in the nervous system. They are also found in the pancreatic islets (D cells), the gastrointestinal mucosa, and the C cells of the thyroid gland (parafollicular cells). Somatostatin is not only secreted into the general circulation as well as locally—it is also secreted into the lumen of the gut, where it may affect gut secretion. A hormone with this activity has been called a **lumone**. Hormones common to the brain, pituitary, and gastrointestinal tract include not only TRH and somatostatin but also VIP and peptides derived from POMC.

Hypothalamic function is regulated both by hormone-mediated signals (eg, negative feedback) and by neural inputs from a wide variety of sources. These nerve signals are mediated by neurotransmitters including acetylcholine, dopamine, norepinephrine, epinephrine, serotonin, GABA, and opioids. The hypothalamus can be considered a final common pathway by which signals from multiple systems reach the anterior pituitary. For example, cytokines that play a role in the response to infection, such as the interleukins, are also involved in regulation of the hypothalamic-pituitary-adrenal axis. This system of immunoneuroendocrine interactions is important in the organism's response to a variety of stresses.

The hypothalamus also sends signals to other parts of the nervous system. For example, while the major nerve tracts of the magnocellular neurons containing vasopressin and oxytocin terminate in the posterior pituitary, nerve fibers from the paraventricular and supraoptic nuclei project toward many other parts of the nervous system. In the brain stem, vasopressinergic neurons are involved in the autonomic regulation of blood pressure. Similar neurons project to the gray matter and are implicated in higher cortical functions. Fibers terminating in the median eminence permit release of ADH into the hypophysial-portal system; delivery of ADH in high concentrations to the anterior pituitary may facilitate its involvement in the regulation of ACTH secretion. Magnocellular neurons also project to the choroid plexus, where they may release ADH into the cerebrospinal fluid. In addition to magnocellular neurons, the

hormone, GnRH. This is achieved through differences in the size and frequency of GnRH release as well as feedback from estrogens and androgens; low-frequency pulses favor FSH release while high-frequency pulses result in LH release. GnRH is a linear decapeptide that stimulates only LH and FSH; it has no effect on other pituitary hormones except in some patients with acromegaly and Cushing disease (see discussion later). The precursor of GnRH—proGnRH—contains 92 amino acids. ProGnRH also contains the sequence of a 56-amino-acid polypeptide called GnRH-associated peptide. This secretory product exhibits PRL-inhibiting activity, but its physiologic role is unknown. GnRH-secreting neurons are located primarily in the preoptic area of the anterior hypothalamus, and their nerve terminals are found in the lateral portions of the external layer of the median eminence adjacent to the pituitary stalk (see Figure 4–2). GnRH has a half-life of 2 to 4 minutes.

paraventricular nuclei contain cells with smaller cell bodies—**parvicellular neurons**. Such neurons are also found in other regions of the nervous system and may contain other peptides such as CRH and TRH.

The Hypothalamus and the Control of Appetite

With the growing appreciation of adipose tissue as an endocrine organ, as well as the increasing problem of obesity and its associated health risks, understanding how energy balance and appetite are regulated has become a major topic of study. In 1901, Frohlich observed that some tumors affecting the pituitary and hypothalamus were associated with excess subcutaneous fat and hypogonadism. Subsequent lesioning experiments by Hetherington and Ranson in the 1940s established the hypothalamus as a fundamental site in the regulation of appetite. These experiments introduced the classic *dual center* model of food intake where the ventromedial hypothalamic nucleus functions as a *satiety center* and the lateral hypothalamic area serves as a *feeding center*. Subsequent studies have led to refinements of this model.

Growing evidence points to the pivotal role of the arcuate nucleus in the integration of feeding signals and energy reserves. It has special access to circulating hormones via the underlying median eminence, an area rich with fenestrated capillaries, that is, it is not protected by the blood–brain barrier (see Figure 4–2). Two populations of neurons involved in the regulation of feeding are located within the arcuate nucleus: one that inhibits food intake via the expression of neuropeptides POMC and cocaine- and amphetamine-regulated transcript, and one that stimulates food intake via expression of neuropeptide Y and agouti-related peptide. The arcuate nucleus projects to second-order neuronal populations including the paraventricular nucleus, dorsomedial nucleus, ventromedial nucleus, and lateral hypothalamic area, which then activate downstream pathways controlling appetite and energy expenditure.

Circulating markers of adiposity (leptin, adiponectin, insulin), and hormones from the gastrointestinal tract (ghrelin, peptide YY, glucagon-like peptide 1, cholecystokinin, oxyntomodulin, pancreatic polypeptide) converge on the hypothalamus and brain stem to signal adequacy of short- and long-term energy stores. Alterations in the levels or tissue sensitivity of these hormones may underlie disorders of weight regulation such as obesity, and could prove useful as therapeutic targets (see also Chapter 20).

The Pineal Gland and the Circumventricular Organs

The circumventricular organs are secretory midline brain structures that arise from the ependymal cell lining of the ventricular system (Figure 4–9). These organs are located adjacent to the third ventricle—subfornical organ, subcommissural organ, organum vasculosum of the lamina terminalis, pineal, and part of the median eminence—and at the roof of the fourth ventricle—area postrema (see Figure 4–9). The tissues of these organs have relatively large interstitial spaces and have fenestrated capillaries
FIGURE 4–9 Circumventricular organs. The neurohypophysis (NH) and adjacent median eminence, the organum vasculosum of the lamina terminalis (OVLT), the subfornical organ (SFO), and the area postrema (AP) are shown projected on a sagittal section of the human brain. The pineal (PI) and the subcommissural organ (SCO) are also shown but probably do not function as circumventricular organs. (Reproduced with permission from Ganong WF. *Review of Medical Physiology*. 15th ed. New York: McGraw-Hill Education; 1993.)

which, being highly permeable, permit diffusion of large molecules from the general circulation; elsewhere in the brain tight capillary endothelial junctions prevent such diffusion—the blood–brain barrier. For example, angiotensin II (see Chapter 10) is involved in the regulation of water intake, blood pressure, and secretion of vasopressin. In addition to its peripheral effects, circulating angiotensin II acts on the subfornical organ resulting in an increase in water intake.

The pineal gland, considered by the 17th century French philosopher René Descartes to be the seat of the soul, is located at the roof of the posterior portion of the third ventricle. The pineal gland in humans and other mammals has no direct neural connections with the brain except for sympathetic innervation via the superior cervical ganglion. The pineal gland secretes melatonin, an indole synthesized from serotonin by 5-methoxylation and *N*-acetylation (Figure 4–10). The pineal releases melatonin into the general circulation and into the cerebrospinal fluid. Melatonin secretion is regulated by the sympathetic nervous system and is increased in response to hypoglycemia and darkness. The pineal also contains other bioactive peptides and amines including TRH, somatostatin, GnRH, and norepinephrine. The physiologic roles of the pineal remain to be elucidated, but they appear to involve regulation of gonadal function and development and chronobiologic rhythms.

The pineal gland may be the site of origin of pineal cell tumors (pinealomas) or germ cell tumors (germinomas). Neurologic signs and symptoms are the predominant clinical manifestations; examples include increased intracranial pressure, visual
FIGURE 4–10 Formation and metabolism of melatonin (HIOMT, hydroxyindole-O-methyltransferase.) (Reproduced with permission from Ganong WF. *Review of Medical Physiology*. 15th ed. New York: McGraw-Hill Education; 1993.)

abnormalities, ataxia, and Parinaud syndrome—upward gaze palsy, absent pupillary light reflex, paralysis of convergence, and wide-based gait. Endocrine manifestations result primarily from deficiency of hypothalamic hormones (diabetes insipidus, hypopituitarism, or disorders of gonadal development). Treatment involves surgical removal or decompression, radiation therapy, and hormone replacement (discussed later).

ANTERIOR PITUITARY HORMONES

The six major anterior pituitary hormones—ACTH, GH, PRL, TSH, LH, and FSH—may be classified into three groups: ACTH-related peptides (ACTH itself, β-lipotropin [β-LPH], melanocyte-stimulating hormone [MSH], and endorphins); the somatomammotropin proteins (GH and PRL); and the glycoproteins (LH, FSH, and TSH). The chemical features of these hormones are set forth in Table 4–2.

ADRENOCORTICOTROPIC HORMONE AND RELATED PEPTIDES

Biosynthesis

ACTH is a 39-amino-acid peptide hormone (MW 4500) processed from a large precursor molecule, POMC (MW 28,500). Within the corticotroph, a single mRNA directs the synthesis and processing of POMC into smaller, biologically active fragments (Figure 4–11), which include β-LPH, α-MSH, β-MSH, β-endorphin, and the amino terminal fragment of POMC. Most of these peptides are glycosylated, which accounts for differences in the reporting of molecular weights. These carbohydrate moieties are responsible for the basophilic staining of corticotrophs.
FIGURE 4–11 The processing of pro-opiomelanocortin (MW 28,500) into its biologically active peptide hormones. Abbreviations are expanded in the text.

Two of these fragments are contained within the structure of ACTH: α-MSH is identical to ACTH 1 to 13, and corticotropin-like intermediate lobe peptide (CLIP) represents ACTH 18 to 39 (see Figure 4–11). Although these fragments are found in species with developed intermediate lobes (eg, the rat), they are not secreted as separate hormones in humans. β-LPH, a fragment with 91 amino acids (1-91), is secreted by the corticotroph in equimolar quantities with ACTH. Within the β-LPH molecule exists the amino acid sequence for β-MSH (41-58), γ-LPH (1-58), and β-endorphin (61-91).

Function

ACTH stimulates the secretion of glucocorticoids, mineralocorticoids, and androgens—all steroids from the adrenal cortex (see Chapters 9 and 10). The amino terminal end (residues 1-18) is responsible for this biologic activity. ACTH binds to receptors on the adrenal cortex and induces steroidogenesis through a cAMP-dependent mechanism.

The hyperpigmentation observed in states of ACTH hypersecretion (eg, Addison disease, Nelson syndrome) appears to be primarily due to ACTH binding to the MSH receptor, because α-MSH and β-MSH do not exist as separate hormones in humans.

The physiologic function of β-LPH and its family of peptide hormones, including β-endorphin, is not completely understood. However, both β-LPH and β-endorphin have the same secretory dynamics as ACTH.

Measurement

The development of immunoradiometric and immunochemiluminescent assays (IRMAs and ICMAs, respectively) has provided a sensitive and practical clinical ACTH assay for the evaluation of pituitary-adrenal disorders. The basal morning concentration ranges from 9 to 52 pg/mL (2-11 pmol/L). Its short plasma half-life (7-12 minutes) and episodic secretion cause wide and rapid fluctuations both in its plasma concentration and in that of cortisol.

Although β-LPH has a longer half-life than ACTH and is more stable in plasma, its measurement has not been extensively utilized. Data suggest that the normal concentration of β-LPH is 10 to 40 pg/mL (1-4 pmol/L).

Secretion

The physiologic secretion of ACTH is mediated through neural influences by means of a complex of hormones, the most important of which is CRH (Figure 4–12).

CRH stimulates ACTH in a pulsatile manner: diurnal rhythmicity causes a peak before awakening and a decline as the day progresses. The diurnal rhythm is a reflection of neural control and provokes concordant diurnal secretion of cortisol from the adrenal cortex (Figure 4–13). This episodic release of ACTH is independent of circulating cortisol levels (ie, the magnitude of an ACTH impulse is not related to preceding plasma cortisol levels). An example is the persistence of diurnal rhythm in patients with primary adrenal failure (Addison disease). ACTH secretion also increases in response to feeding in both humans and animals.
FIGURE 4–12 The hypothalamic-pituitary-adrenal axis, illustrating negative feedback by cortisol (F) at the hypothalamic and pituitary levels. A short negative feedback loop of ACTH on the secretion of corticotropin-releasing hormone (CRH) also exists. (Reproduced with permission from Gwinup G, Johnson B. Clinical testing of the hypothalamic-pituitary-adrenocortical system in states of hypo- and hypercortisolism. *Metabolism*. 1975 Jun;24(6):777-791.)

Many stresses stimulate ACTH, often superseding the normal diurnal rhythmicity. Physical, emotional, and chemical stresses such as pain, trauma, hypoxia, acute hypoglycemia, cold exposure, surgery, depression, and interleukin-1 and vasopressin administration have all been shown to stimulate ACTH and cortisol secretion. The increase in ACTH levels during stress is mediated by vasopressin as well as CRH. Although physiologic cortisol levels do not blunt the ACTH response to stress, exogenous corticosteroids in high doses suppress it.

Negative feedback of cortisol and synthetic glucocorticoids on ACTH secretion occurs at both the hypothalamic and pituitary levels via two mechanisms: fast feedback is sensitive to the rate of change in cortisol levels, whereas slow feedback is sensitive to the absolute cortisol level. The first mechanism is probably nonnuclear; that is, this phenomenon occurs too rapidly to be explained by the influence of corticosteroids on nuclear transcription of the specific mRNA responsible for ACTH. Recent studies suggest fast feedback is mediated by a novel membrane-associated glucocorticoid receptor that stimulates a rapid synthesis and retrograde release of endocannabinoids, thereby suppressing synaptic excitation. Slow feedback, occurring later, may be explained by a nuclear-mediated mechanism and a subsequent decrease in synthesis of ACTH. This latter form of negative feedback is the type probed by the clinical dexamethasone suppression test. In addition to the negative feedback of corticoids, ACTH also inhibits its own secretion (short-loop feedback).
FIGURE 4–13 The episodic, pulsatile pattern of ACTH secretion and its concordance with cortisol secretion in a healthy human subject during a 24-hour period. (Used with permission from Johannes D. Veldhuis, MD.)

GROWTH HORMONE

Biosynthesis

GH or somatotropin is a 191-amino-acid polypeptide hormone (MW 21,500) synthesized and secreted by the somatotrophs of the anterior pituitary. Its larger precursor peptide, pre-GH (MW 28,000), is also secreted but has no physiologic significance.

Function

The primary function of GH is promotion of linear growth. Its basic metabolic effects serve to achieve this result, but most of the growth-promoting effects are mediated by insulin-like growth factor 1 (IGF-1; previously known as somatomedin C). The metabolic and biologic effects of GH and IGF-1 are shown in Tables 4–5 and 4–6 (see also Chapter 6).

GH, via IGF-1, increases protein synthesis by enhancing amino acid uptake and directly accelerating the transcription and translation of mRNA. In addition, GH tends to decrease protein catabolism by mobilizing fat as a more efficient fuel source: it directly causes the release of fatty acids from adipose tissue and enhances their conversion to acetyl-CoA, from which energy is derived. This protein-sparing effect is an important mechanism by which GH promotes growth and development.

GH also affects carbohydrate metabolism. In excess, it decreases carbohydrate utilization and impairs glucose uptake into cells. This GH-induced insulin resistance appears to be due to a postreceptor impairment in insulin action. These events result in glucose intolerance and secondary hyperinsulinism.

Measurement

GH has a plasma half-life of 10 to 20 minutes. The healthy adult secretes approximately 400 µg/d (18.6 nmol/d); in contrast, young adolescents secrete about 700 µg/d (32.5 nmol/d). The early morning GH concentration in fasting unstressed adults is less than 2 ng/mL (90 pmol/L). There are no significant sex differences.

About half of circulating GH is bound to specific GH-binding proteins (GHBPs) that function to reduce oscillations in GH levels (due to its pulsatile secretion) and prolong plasma GH half-life. GHBPs include a high-affinity GHBP (corresponding to the extracellular portion of the GH receptor formed through

TABLE 4–5 Metabolic effects of GH and IGF-1 *in vivo.*

Function, Parameter Group	Function, Parameter Subgroup	GH	IGF-1

proteolytic cleavage) and a low-affinity species. Measurement of serum concentrations of the high-affinity GHBP provides an index of GH receptor concentrations. For example, individuals with Laron dwarfism, a form of GH insensitivity characterized by mutations in the GH receptor, usually have abnormally low levels of GHBP.

Concentrations of IGF-1 are determined by radioreceptor assays or radioimmunoassays. Determining the levels of these mediators of GH action may result in more accurate assessment of the biologic activity of GH (see Chapter 6).

Secretion

The secretion of GH is predominantly mediated by two hypothalamic hormones: GHRH and somatostatin (GHIH), both of which contribute to the episodic pattern of GH secretion. These hypothalamic influences are tightly regulated by an integrated system of neural, metabolic, and hormonal factors. Table 4–7 summarizes the many factors that affect GH secretion in physiologic, pharmacologic, and pathologic states.

A. Growth hormone–releasing hormone   GHRH binds to specific receptors, stimulating cAMP production by somatotrophs and stimulating both GH synthesis and secretion. The effects of GHRH are partially blocked by somatostatin. The administration of GHRH to normal humans leads to rapid release of GH (within minutes); levels peak at 30 minutes and are sustained for 60 to 120 minutes.

Other peptide hormones such as ADH, ACTH, and α-MSH may act as GH-releasing factors when present in pharmacologic amounts. Even TSH and GnRH often cause GH secretion in patients with acromegaly; however, it is not certain whether any of these effects are mediated by the hypothalamus or represent direct effects on the somatotroph. Regulation of GHRH is primarily

under neural control (see discussion later), but there is also short-loop negative feedback by GHRH itself.

B. Somatostatin   Somatostatin, a tetradecapeptide, is a potent inhibitor of GH secretion. It decreases cAMP production in GH-secreting cells and inhibits both basal and stimulated GH secretion. Somatostatin secretion is increased by elevated levels of GH and IGF-1. Long-acting analogs of somatostatin have been used therapeutically in the management of GH excess and in conditions such as pancreatic and carcinoid tumors that cause diarrhea.

C. Growth hormone secretagogues   Non-GHRH secretagogues act to release GH, not through the GHRH receptor, but through a separate receptor, the growth hormone secretagogue receptor (GHS-R). A number of synthetic secretagogues, both peptides and nonpeptides, have been described. **Ghrelin**, a circulating peptide made by endocrine cells in the stomach, is the endogenous ligand for GHS-R (now termed ghrelin receptor). Its location in the stomach suggests a new mechanism for regulation of GH secretion.

D. Neural control   The neural control of basal GH secretion results in irregular and intermittent release associated with sleep and varying with age. Peak levels occur 1 to 4 hours after the onset of sleep (during stages 3 and 4) (Figure 4–14). These nocturnal sleep bursts, which account for nearly 70% of daily GH secretion, are greater in children and tend to decrease with age. Glucose infusion does not suppress this episodic release. Emotional, physical, and chemical stress, including surgery, trauma, exercise, electroshock therapy, and pyrogen administration, provoke GH release. In addition, impairment of secretion leading to growth failure has been well documented in children with severe emotional deprivation (see Chapter 6).

[a]Suppressive effects of some factors can be demonstrated only in the presence of a stimulus.

Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism*. 3rd ed. New York: McGraw-Hill Education; 1995.

E. Metabolic control   The metabolic factors affecting GH secretion include all fuel substrates: carbohydrate, protein, and fat. Glucose administration, orally or intravenously, lowers GH in healthy subjects and provides a simple physiologic maneuver useful in the diagnosis of acromegaly (see discussed later). In contrast, hypoglycemia stimulates GH release. This effect depends on intracellular glycopenia, because the administration of 2-deoxyglucose (a glucose analog that causes intracellular glucose deficiency) also increases GH. This response to hypoglycemia depends on both the rate of change in blood glucose and the absolute level attained.

A protein meal or intravenous infusion of amino acids (eg, arginine) causes GH release. Paradoxically, states of protein-calorie malnutrition also increase GH, possibly as a result of decreased IGF-1 production and lack of inhibitory feedback.

Fatty acids suppress GH responses to certain stimuli, including arginine and hypoglycemia. Fasting stimulates GH secretion, pos-

sibly as a means of mobilizing fat as an energy source and preventing protein loss.

F. Effects of other hormones   Responses to stimuli are blunted in states of cortisol excess and during hypo- and hyperthyroidism. Estrogen enhances GH secretion in response to stimulation.

G. Effects of neuropharmacologic agents   Many neurotransmitters and neuropharmacologic agents affect GH secretion. Biogenic amine agonists and antagonists act at the hypothalamic level and alter GHRH or somatostatin release. Dopaminergic, alpha-adrenergic, and serotonergic agents all stimulate GH release.

Dopamine agonists such as levodopa, apomorphine, and bromocriptine increase GH secretion, whereas dopaminergic antagonists such as phenothiazines inhibit GH. The effect of levodopa, a precursor of both norepinephrine and dopamine, may be mediated by its conversion to norepinephrine, because its effect is blocked by the alpha-adrenergic antagonist phentolamine. Moreover, phentolamine suppresses GH release in response to other stimuli such as hypoglycemia, exercise, and arginine, emphasizing the importance of alpha-adrenergic mechanisms in modulating GH secretion.

Beta-adrenergic agonists inhibit GH, and beta-adrenergic antagonists such as propranolol enhance secretion in response to provocative stimuli.

PROLACTIN

Biosynthesis

PRL is a 198-amino-acid polypeptide hormone (MW 22,000) synthesized and secreted from the lactotrophs of the anterior pituitary. Despite evolution from an ancestral hormone common to GH and human placental lactogen (hPL), PRL shares only 16% of its residues with the former and 13% with hPL. A precursor molecule (MW 40,000-50,000) is also secreted and may constitute 8% to 20% of the PRL plasma immunoreactivity in healthy persons and in patients with PRL-secreting pituitary tumors. PRL and GH are structurally related to members of the cytokine-hematopoietin family that include erythropoietin, granulocyte-macrophage colony stimulating factor (GM-CSF), and interleukins IL-2 to IL-7.

Function

PRL stimulates lactation in the postpartum period (see Chapter 16). During pregnancy, PRL secretion increases and, in concert with many other hormones (estrogen, progesterone, hPL, insulin, and cortisol), promotes additional breast development in preparation for milk production. Despite its importance during pregnancy, PRL has not been demonstrated to play a role in the development of normal breast tissue in humans. During pregnancy, estrogen enhances breast development but blunts the effect of PRL on lactation; the decrease in both estrogen and progesterone after parturition allows initiation of lactation. Accordingly, galactorrhea
FIGURE 4–14 Sleep-associated changes in prolactin (PRL) and growth hormone (GH) secretion in humans. Peak levels of GH occur during sleep stages 3 or 4; the increase in PRL is observed 1 to 2 hours after sleep begins and is not associated with a specific sleep phase. (Reproduced with permission from Sassin JF, Frantz AG, Weitzman ED, et al. Human prolactin: 24-hour pattern with increased release during sleep. *Science*. 1972 Sep 29;177(4055):1205-1207.)

may accompany the discontinuance of oral contraceptives or estrogen therapy. Although basal PRL secretion falls in the postpartum period, lactation is maintained by persistent breast suckling.

PRL levels are very high in the fetus and in newborn infants, declining during the first few months of life.

Although PRL does not appear to play a physiologic role in the regulation of gonadal function, hyperprolactinemia in humans leads to hypogonadism. In women, initially there is a shortening of the luteal phase; subsequently, anovulation, oligomenorrhea or amenorrhea, and infertility occur. In men, PRL excess leads to decreased testosterone synthesis and decreased spermatogenesis, which clinically present as decreased libido, impotence, and infertility. The exact mechanisms of PRL inhibition of gonadal function are unclear, but the principal one appears to be alteration of hypothalamic-pituitary control of gonadotropin secretion. Basal LH and FSH levels are usually normal; however, their pulsatile secretion is decreased and the midcycle LH surge is suppressed in women. Gonadotropin reserve, as assessed by administration of exogenous GnRH, is usually normal. PRL also has a role in immunomodulation; extrapituitary synthesis of PRL occurs in T lymphocytes (among other sites), and PRL receptors are present on T and B lymphocytes and macrophages. PRL modulates and stimulates both immune cell proliferation and survival.

Measurement

The PRL secretory rate is approximately 400 μg/d (18.6 nmol/d). The hormone is cleared by the liver (75%) and the kidney (25%), and its half-time of disappearance from plasma is about 25 to 50 minutes.

Basal levels of PRL in adults vary considerably, with a mean of 13 ng/mL (0.6 nmol/L) in women and 5 ng/mL (0.23 nmol/L)

in men. The upper range of normal in most laboratories is 15 to 20 ng/mL (0.7-0.9 nmol/L).

PRL is measured using a highly specific immunoradiometric assay. However, when PRL levels are extremely high, which can occur with some PRL-secreting tumors, this assay may be susceptible to the "hook effect." PRL levels are erroneously reported as normal or modestly elevated due to saturation of available assay antibodies. Appropriate sample dilutions (ie, 1:100) will avoid this artifact.

In some patients a form of PRL with molecular mass greater than 150 kDa predominates. This is termed *macroprolactinemia* and consists of aggregates of monomeric PRL as well as PRL-immunoglobulin G complexes. These complexes may have reduced biological activity and can be measured using polyethylene glycol precipitation of serum samples.

Secretion

The hypothalamic control of PRL secretion is predominantly inhibitory, and dopamine is the most important inhibitory factor. The physiologic, pathologic, and pharmacologic factors influencing PRL secretion are listed in Table 4–8.

A. Prolactin-releasing factors   TRH is a potent PRL-releasing factor that evokes release of PRL at a threshold dose similar to that which stimulates release of TSH. An exaggerated response of both TSH and PRL to TRH is observed in primary hypothyroidism, and their responses are blunted in hyperthyroidism. In addition, PRL secretion is also stimulated by VIP and serotonergic pathways.

B. Episodic and sleep-related secretion   PRL secretion is episodic. An increase is observed 60 to 90 minutes after sleep

begins but—in contrast to GH—is not associated with a specific sleep phase. Peak levels are usually attained between 4 and 7 AM (see Figure 4–14). This sleep-associated augmentation of PRL release is not part of a circadian rhythm, like that of ACTH; it is related strictly to the sleeping period regardless of when it occurs during the day.

C. Other stimuli   Stresses, including surgery, exercise, hypoglycemia, and acute myocardial infarction, cause significant elevation of PRL levels. Nipple stimulation in nonpregnant women also increases PRL. This neurogenic reflex may also occur from chest wall injury such as mechanical trauma, burns, surgery, and herpes zoster of thoracic dermatomes. This reflex discharge of PRL is abolished by denervation of the nipple or by spinal cord or brain stem lesions.

D. Effects of other hormones   Many hormones influence PRL release. Estrogens augment basal and stimulated PRL secretion after 2 to 3 days of use (an effect that is of special clinical importance in patients with PRL-secreting pituitary adenomas); glucocorticoids tend to suppress TRH-induced PRL secretion; and thyroid hormone administration may blunt the PRL response to TRH.

E. Effects of pharmacologic agents (Table 4–8)   Many pharmacologic agents alter PRL secretion. Dopamine agonists (eg,

bromocriptine) decrease secretion, forming the basis for their use in states of PRL excess. Dopamine antagonists (eg, receptor blockers such as phenothiazines and metoclopramide) and dopamine depletors (eg, reserpine) augment PRL release. Serotonin agonists enhance PRL secretion; serotonin receptor blockers suppress PRL release associated with stress and with nursing.

THYROTROPIN

Biosynthesis

TSH is a glycoprotein (MW 28,000) composed of two noncovalently linked alpha and beta subunits. The structure of the alpha subunit of TSH is identical to that of the other glycoprotein molecules—FSH, LH, and hCG—but the beta subunits differ in these glycoproteins and is responsible for their biologic and immunologic specificity. The peptides of these subunits appear to be synthesized separately and united before the carbohydrate groups are attached. The intact molecule is then secreted, as are small amounts of nonlinked subunits.

Function

The beta subunit of TSH attaches to high-affinity receptors in the thyroid, stimulating iodide uptake, hormonogenesis, and release of T_4 and T_3. This occurs through activation of adenylyl cyclase and the generation of cAMP. TSH secretion also causes an increase in gland size and vascularity by promoting mRNA and protein synthesis. (For a more detailed description, see Chapter 7.)

Measurement

TSH circulates unbound in the blood with a half-life of 35 to 50 minutes. With ultrasensitive immunometric assays for measuring TSH concentration, the normal range is usually 0.5 to 4.7 μU/mL (0.5-4.7 mU/L). Measurement of TSH is the most sensitive screening test for the diagnosis of primary hypothyroidism and hyperthyroidism; however, TSH levels alone cannot be used to evaluate pituitary or hypothalamic hypothyroidism.

The alpha subunit can be detected in about 80% of normals, with a range of 0.5 to 2 ng/mL. Plasma alpha subunit levels increase after administration of TRH in normal subjects, and basal levels are elevated in primary hypothyroidism, primary hypogonadism, and in patients with TSH-secreting, gonadotropin-secreting, or pure alpha subunit-secreting pituitary adenomas.

Secretion

The secretion of TSH is controlled by both stimulatory (TRH) and inhibitory (somatostatin) influences from the hypothalamus and in addition is modulated by the feedback inhibition of thyroid hormone on the hypothalamic-pituitary axis.

A. TRH   The response of TSH to TRH is modulated by the circulating concentration of thyroid hormones. Small changes in serum levels (even within the physiologic range) cause substantial alterations in the TSH response to TRH. As shown in
FIGURE 4–15 Administration of small doses of T_3 (15 µg) and T_4 (60 µg) to healthy subjects inhibits the TSH response to two doses (400 µg, left; 25 µg, right) of TRH (protirelin). (Reproduced with permission from Snyder PJ, Utiger RD. Inhibition of thyrotropin-releasing hormone by small quantities of thyroid hormones. *J Clin Invest.* 1972 Aug;51(8):2077-2084.)

Figure 4–15, the administration of T_3 (15 µg) and T_4 (60 µg) to healthy persons for 3 to 4 weeks suppresses the TSH response to TRH despite only small increases in circulating T_3 and T_4 levels. Thus, the secretion of TSH is inversely proportional to the concentration of thyroid hormone.

The set point (the level at which TSH secretion is maintained) is determined by TRH. Deviations from this set point result in appropriate changes in TSH release. Administration of TRH increases TSH within 2 minutes, and this response is blocked by previous T_3 administration; however, larger doses of TRH may overcome this blockade—suggesting that both T_3 and TRH act at the pituitary level to influence TSH secretion. In addition, T_3 and T_4 inhibit mRNA for TRH synthesis in the hypothalamus, indicating that a negative feedback mechanism operates at this level also.

B. Somatostatin This inhibitory hypothalamic peptide augments the direct inhibitory effect of thyroid hormone on the thyrotrophs. Infusion of somatostatin blunts the early morning TSH surge and suppresses high levels of TSH in primary hypothyroidism. Octreotide acetate, a somatostatin analog, has been used successfully to inhibit TSH secretion in patients with TSH-secreting pituitary tumors.

C. Neural control In addition to these hypothalamic influences on TSH secretion, neurally mediated factors may be important. Dopamine physiologically inhibits TSH secretion. Intravenous dopamine administration decreases TSH in both healthy and hypothyroid subjects as well as blunts the TSH response to TRH. Thus, as expected, dopaminergic agonists such as bromocriptine

inhibit TSH secretion and dopaminergic antagonists such as metoclopramide increase TSH secretion in euthyroid subjects.

D. Effects of cortisol and estrogens Glucocorticoid excess has been shown to impair the sensitivity of the pituitary to TRH and may lower serum TSH to undetectable levels. However, estrogens increase the sensitivity of the thyrotroph to TRH; women have a greater TSH response to TRH than men do, and pretreatment of men with estradiol increases their TRH-induced TSH response. (See also Chapter 7.)

E. Other Serum TSH levels exhibit a diurnal variation with the peak occurring around midnight and the nadir at 8 to 10 AM. TSH levels are also higher in older individuals and those with higher body mass indices although the relationship is poorly understood (TSH decreases in patients who lose weight after bariatric surgery). Some authorities advocate for a higher TSH goal in elderly patients (TSH of 4 to 6 µU/mL for age >70 years).

GONADOTROPINS: LUTEINIZING HORMONE (LH) AND FOLLICLE-STIMULATING HORMONE (FSH)

Biosynthesis

LH and FSH are glycoprotein gonadotropins composed of alpha and beta subunits and secreted by the same cell. The specific beta subunit confers on these hormones their unique biologic activity,

as it does with TSH and hCG. The biologic activity of hCG, a placental glycoprotein, closely resembles that of LH. Human menopausal gonadotropin (hMG, menotropins)—an altered mixture of pituitary gonadotropins recovered from the urine of postmenopausal women—is a preparation with FSH-like activity. Menotropins and hCG are used clinically for induction of spermatogenesis or ovulation (see Chapters 12 and 13).

Function

LH and FSH bind to receptors in the ovary and testis and regulate gonadal function by promoting sex steroid production and gametogenesis.

In men, LH stimulates testosterone production from the interstitial cells of the testes (Leydig cells). Maturation of spermatozoa, however, requires both LH and FSH. FSH stimulates testicular growth and enhances the production of an androgen-binding protein by the Sertoli cells, which are a component of the testicular tubule necessary for sustaining the maturing sperm cell. This androgen-binding protein promotes high local concentrations of testosterone within the testis, an essential factor in the development of normal spermatogenesis (see Chapter 12).

In women, LH stimulates estrogen and progesterone production from the ovary. A surge of LH in the mid-menstrual cycle is responsible for ovulation, and continued LH secretion subsequently stimulates the corpus luteum to produce progesterone by enhancing the conversion of cholesterol to pregnenolone. Development of the ovarian follicle is largely under FSH control, and the secretion of estrogen from this follicle is dependent on both FSH and LH.

Measurement

The normal levels of LH and FSH vary with the age of the subject (see Appendix). They are low before puberty and elevated in postmenopausal women. A nocturnal rise of LH in boys and the cyclic secretion of FSH and LH in girls usually herald the onset of puberty before clinical signs are apparent. In women, LH and FSH vary during the menstrual cycle; during the initial phase of the cycle (follicular), LH steadily increases, with a midcycle surge that initiates ovulation. FSH, on the other hand, initially rises and then decreases during the later follicular phase until the midcycle surge, which is concordant with LH. Both LH and FSH levels fall steadily after ovulation (see Chapter 13).

LH and FSH levels in men are similar to those in women during the follicular phase. The alpha subunit, shared by all the pituitary glycoprotein hormones, can also be measured (see TSH) and will rise following GnRH administration.

Secretion

The secretion of LH and FSH is controlled by GnRH, which maintains basal gonadotropin secretion, generates the phasic release of gonadotropins for ovulation, and determines the onset of puberty. As noted earlier, the size and frequency of GnRH pulses determine the ratio of gonadotropin secretion: low-frequency pulses favor FSH release while high-frequency pulses result in LH release. Many other factors are involved in regulation of this axis. For example, activins and follistatins are paracrine factors that exert opposing effects on gonadotrophs. Leptin, a hormone made in adipocytes in proportion to fat stores, is involved in regulation of this axis and may help to explain the suppression of gonadotropin secretion that accompanies caloric restriction.

A. Episodic secretion   In both males and females, secretion of LH and FSH is episodic, with secretory bursts that occur each hour and are mediated by a concordant episodic release of GnRH. The amplitude of these secretory surges is greater in patients with primary hypogonadism. The pulsatile nature of GnRH release is critical for sustaining gonadotropin secretion. A continuous, prolonged infusion of GnRH in women evokes an initial increase in LH and FSH followed by prolonged suppression of gonadotropin secretion. This phenomenon may be explained by downregulation of GnRH receptors on the pituitary gonadotrophs. Consequently, long-acting synthetic analogs of GnRH may be used clinically to suppress LH and FSH secretion in conditions such as precocious puberty.

B. Positive feedback   Circulating sex steroids affect GnRH secretion and thus LH and FSH secretion by both positive and negative (inhibitory) feedback mechanisms. During the menstrual cycle, estrogens provide a positive influence on GnRH effects on LH and FSH secretion, and the rise in estrogen during the follicular phase is the stimulus for the LH and FSH ovulatory surge. This phenomenon suggests that the secretion of estrogen is to some extent influenced by an intrinsic ovarian cycle. Progesterone amplifies the duration of the LH and FSH surge and augments the effect of estrogen. After this midcycle surge, the developed egg leaves the ovary. Ovulation occurs approximately 10 to 12 hours after the LH peak and 24 to 36 hours after the estradiol peak. The remaining follicular cells in the ovary are converted, under the influence of LH, to a progesterone-secreting structure, the corpus luteum. After about 12 days, the corpus luteum involutes, resulting in decreased estrogen and progesterone levels and then uterine bleeding (see Chapter 13).

C. Negative feedback   Negative feedback effects of sex steroids on gonadotropin secretion also occur. In women, primary gonadal failure or menopause results in elevations of LH and FSH, which can be suppressed with long-term, high-dose estrogen therapy. However, a shorter duration of low-dose estrogen may enhance the LH response to GnRH. In men, primary gonadal failure with low circulating testosterone levels is also associated with elevated gonadotropins. However, testosterone is not the sole inhibitor of gonadotropin secretion in men, since selective destruction of the tubules (eg, by cyclophosphamide therapy) results in azoospermia and elevation of only FSH.

Inhibin, a polypeptide (MW 32,000) secreted by the Sertoli cells of the seminiferous tubules, is the major factor that inhibits FSH secretion by negative feedback. Inhibin consists of separate alpha and beta subunits connected by a disulfide bridge. Androgens stimulate inhibin production; this peptide may help to locally regulate spermatogenesis (see Chapter 12).

ENDOCRINOLOGIC EVALUATION OF THE HYPOTHALAMIC-PITUITARY AXIS

The precise assessment of the hypothalamic-pituitary axis has been made possible by immunoassays of the major anterior pituitary hormones and their specific target gland hormones. In addition, provocative testing using synthetic or purified hormones (eg, ACTH, ovine CRH, glucagon, and insulin) can be used to assess hypothalamic-pituitary reserve and excess.

This section describes the principles involved in testing each pituitary hormone as well as special situations (eg, drugs, obesity) that may interfere with pituitary function or pituitary testing. Specific protocols for performing and interpreting diagnostic procedures are outlined at the end of this section and in Table 4–9. The clinical manifestations of either hypo- or hypersecretion of anterior pituitary hormones are discussed in subsequent sections.

EVALUATION OF ADRENOCORTICOTROPIC HORMONE

ACTH deficiency leads to secondary adrenocortical insufficiency, characterized by decreased secretion of cortisol and the adrenal androgens; aldosterone secretion, controlled primarily by the renin-angiotensin axis, is usually maintained. In contrast, excessive ACTH secretion leads to adrenal hyperfunction (Cushing syndrome, discussed in a later section of this chapter and in Chapter 9).

Plasma ACTH Levels

Basal ACTH measurements are usually unreliable indicators of pituitary function, because its short plasma half-life and episodic secretion result in wide fluctuations in plasma levels (see Figure 4–13). Therefore, the interpretation of plasma ACTH levels requires the simultaneous assessment of cortisol secretion by the adrenal cortex. These measurements are of greatest utility in differentiating primary and secondary adrenocortical insufficiency and in establishing the etiology of Cushing syndrome (see the later section on Cushing disease and also Chapter 9).

Evaluation of ACTH Deficiency

In evaluating ACTH deficiency, measurement of basal cortisol levels is also generally unreliable. Because plasma cortisol levels are usually low in the late afternoon and evening, reflecting the normal diurnal rhythm, samples drawn at these times are of virtually no value for this diagnosis. Plasma cortisol levels are usually highest in the early morning; however, there is considerable overlap between adrenal insufficiency and normal subjects. A plasma cortisol level less than 5 μg/dL (138 nmol/L) at 8 AM strongly suggests the diagnosis—and the lower the level, the more likely the diagnosis. Conversely, a plasma cortisol greater than 20 μg/dL (552 nmol/L) virtually excludes the diagnosis. Similarly, salivary cortisol levels less than 1.8 ng/mL (5 nmol/L) at 8 AM strongly suggest adrenal insufficiency, while levels in excess of 5.8 ng/mL

(16 nmol/L) greatly reduce the probability of the diagnosis. Consequently, the diagnosis of ACTH hyposecretion (secondary adrenal insufficiency) must be established by provocative testing of the reserve capacity of the hypothalamic-pituitary axis.

Adrenal Stimulation

Because adrenal atrophy develops as a consequence of prolonged ACTH deficiency, the initial and most convenient approach to evaluation of the hypothalamic-pituitary-adrenal axis is assessment of the plasma cortisol response to synthetic ACTH (cosyntropin). In normal individuals, injection of cosyntropin (250 μg) causes a rapid increase (within 30 minutes) of cortisol to at least 18 to 20 μg/dL (496-552 nmol/L), and this response usually correlates with the cortisol response to insulin-induced hypoglycemia (typically considered the gold standard in the diagnosis of adrenocortical insufficiency). With the introduction of more specific cortisol assays (eg, tandem mass spectrometry), the normal peak cortisol response following ACTH stimulation may be lower than currently accepted ranges. A subnormal cortisol response to ACTH confirms adrenocortical insufficiency. However, a normal response does not directly evaluate the ability of the hypothalamic-pituitary axis to respond to stress (see Chapter 9). Thus, patients withdrawn from long-term glucocorticoid therapy may have an adequate increase in cortisol following exogenous ACTH that precedes complete recovery of the hypothalamic-pituitary-adrenal axis. Therefore, such patients should receive glucocorticoids during periods of stress for at least 1 year after steroids are discontinued, unless the hypothalamic-pituitary axis is shown to be responsive to stress as described later.

The more physiologic dose administered in the 1 μg ACTH test is designed to improve its sensitivity in detection of secondary adrenal insufficiency. The cortisol response to 1 μg of synthetic ACTH correlates better with the cortisol response to insulin-induced hypoglycemia in patients with complete chronic secondary adrenal insufficiency. However, the results in partial secondary adrenal insufficiency are less reliable and technical difficulties make the test impractical for routine use. Thus, the standard 250 μg ACTH test remains the procedure of choice (see discussion later and Chapter 9).

Pituitary Stimulation

Direct evaluation of pituitary ACTH reserve can be performed by means of insulin-induced hypoglycemia, metyrapone administration, or CRH stimulation. These studies are unnecessary if the cortisol response to rapid ACTH stimulation is subnormal.

A. Insulin-induced hypoglycemia The stimulus of neuroglycopenia associated with hypoglycemia (blood glucose <40 mg/dL) evokes a stress-mediated activation of the hypothalamic-pituitary-adrenal axis. Subjects should experience adrenergic symptoms (diaphoresis, tachycardia, weakness, headache) associated with the fall in blood sugar. In normal persons, plasma cortisol increases to more than 18 to 20 μg/dL (496-552 nmol/L), indicating normal ACTH reserve. Although plasma ACTH also rises, its

TABLE 4–9 Endocrine tests of hypothalamic-pituitary function.

	Method	Sample Collection	Possible Side Effects; Contraindications	Interpretation
Rapid ACTH stimulation test (cosyntropin test)	Administer synthetic ACTH (1-24) (cosyntropin), 250 µg intravenously or intramuscularly. The test may be performed at any time of the day or night and does not require fasting. The low-dose test is performed in the same manner except that 1 µg of synthetic ACTH (1-24) is administered.	Obtain samples for plasma cortisol at 0 and 30 min or at 0 and 60 min.	Rare allergic reactions have been reported.	A normal response is a peak plasma cortisol level >18-20 µg/dL (496-552 nmol/L).
Insulin hypoglycemia test	Give nothing by mouth after midnight. Start an intravenous infusion with normal saline solution. Regular insulin is given intravenously in a dose sufficient to cause adequate hypoglycemia (blood glucose <40 mg/dL). The dose is 0.1-0.15 unit/kg (healthy subjects); 0.2-0.3 unit/kg (obese subjects or those with Cushing syndrome or acromegaly); 0.05 unit/kg (patients with suspected hypopituitarism).	Collect blood for glucose determinations every 15 min during the study. Samples of GH and cortisol are obtained at 0, 30, 45, 60, 75, and 90 min.	A physician must be in attendance. Symptomatic hypoglycemia (diaphoresis, headache, tachycardia, weakness) is necessary for adequate stimulation and occurs 20-35 min after insulin is administered in most patients. If severe central nervous system signs or symptoms occur, intravenous glucose (25-50 mL of 50% glucose) should be given immediately; otherwise, the test can be terminated with a meal or with oral glucose. This test is contraindicated in the elderly or in patients with cardiovascular or cerebrovascular disease and seizure disorders.	Symptomatic hypoglycemia and a fall in blood glucose to <40 mg/dL (2.2 mmol/L) will increase GH to a maximal level >5 ng/mL; some investigators regard an increment of 6 ng/mL (280 pmol/L) as normal. Plasma cortisol should increase to a peak level of at least 18-20 µg/dL (496-552 nmol/L).
Metyrapone test	Metyrapone is given orally between 11 and 12 PM with a snack to minimize gastrointestinal discomfort. The dose is 30 mg/kg.	Blood for plasma 11-deoxycortisol and cortisol determinations is obtained at 8 AM the morning after metyrapone is given.	Gastrointestinal upset may occur. Adrenal insufficiency may occur. Metyrapone should not be used in sick patients or those in whom primary adrenal insufficiency is suspected.	Serum 11-deoxycortisol should increase to >7 µg/dL (190 nmol/L). Cortisol should be <10 µg/dL (280 nmol/L) in order to ensure adequate inhibition of 11β-hydroxylation.
Glucagon stimulation test	The patient should be fasting after midnight. Give glucagon 1 mg intramuscularly.	Blood for plasma GH and capillary blood glucose at 0, 30, 60, 90, 120, 150, and 180 min.	Nausea and late hypoglycemia. This test is contraindicated in malnourished patients or patients who have not eaten for >48 h.	GH rises to >3 ng/mL in normal individuals. Glucose usually rises to peak around 90 min, then gradually declines.
Glucose growth hormone suppression test	The patient should be fasting after midnight; give glucose, 75-100 g orally.	GH and glucose should be determined at 0, 30, and 60 min after glucose administration.	Patients may complain of nausea after the large glucose load.	GH levels are suppressed to <2 ng/mL (90 pmol/L) in healthy subjects. Failure of adequate suppression or a paradoxic rise may be seen in acromegaly, starvation, protein-calorie malnutrition, and anorexia nervosa.
Clomiphene test	Clomiphene is administered orally. For women, give 100 mg daily for 5 d (beginning on day 5 of the cycle if the patient is menstruating); for men, give 100 mg daily for 7-10 d.	Blood for LH and FSH determinations is drawn before and after clomiphene is given.	This drug may stimulate ovulation, and women should be advised accordingly.	In women, LH and FSH levels peak on the fifth day to a level above the normal range. After the fifth day, LH and FSH levels decline. In men, LH should double after 1 wk; FSH will also increase, but to a lesser extent.

(Continued)

TABLE 4–9 Endocrine tests of hypothalamic-pituitary function. (*Continued*)

	Method	Sample Collection	Possible Side Effects; Contraindications	Interpretation
CRH test	CRH (1 µg/kg) is given intravenously as a bolus injection.	Blood samples for ACTH and cortisol are taken at 0, 15, 30, and 60 min.	Flushing often occurs. Transient tachycardia and hypotension have also been reported.	The ACTH response is dependent on the assay utilized and occurs 15 min after CRH is administered. The peak cortisol response occurs at 30-60 min and is usually >10 µg/dL (276 nmol/L).
Low-dose dexamethasone suppression test	Dexamethasone (1 mg) is given between 11 PM and midnight.	Blood samples for cortisol and dexamethasone are taken at 8 AM the next morning.	Side effects are rare. Compliance is sometimes an issue. Some medications and patient variability can affect dexamethasone metabolism.	Cortisol should suppress to <1.8 µg/dL (50 nmol/L) in normal individuals. This cutoff has a high sensitivity, but specificity is compromised.

determination has not proved to be as useful, because pulsatile secretion requires frequent sampling, and the normal response is not well standardized. Although insulin-induced hypoglycemia most reliably predicts ACTH secretory capacity in times of stress, it is rarely performed at present, because the procedure requires a physician's presence and is contraindicated in elderly patients, patients with cerebrovascular or cardiovascular disease, and those with seizure disorders. It should be used with caution in patients in whom diminished adrenal reserve is suspected, because severe hypoglycemia may occur; in these patients, the test should always be preceded by the ACTH adrenal stimulation test.

B. Metyrapone stimulation   Metyrapone administration is an alternative method for assessing ACTH secretory reserve. Metyrapone inhibits P450c11 (11β-hydroxylase), the enzyme that catalyzes the final step in cortisol biosynthesis (see Chapter 9). The inhibition of cortisol secretion interrupts negative feedback on the hypothalamic-pituitary axis, resulting in a compensatory increase in ACTH. The increase in ACTH secretion stimulates increased steroid biosynthesis proximal to P450c11, and the increase can be detected as an increase in the precursor steroid (11-deoxycortisol) in plasma. The overnight test is preferred because of its simplicity; it is performed by administering 30 mg/kg of metyrapone orally at midnight. Plasma 11-deoxycortisol is determined the following morning and rises to more than 7 µg/dL (0.2 nmol/L) in healthy individuals. Again, the test should be used cautiously in patients with suspected adrenal insufficiency and should be preceded by a rapid ACTH stimulation test (see discussion earlier). The traditional 3-day metyrapone test should not be used at present because of the risk of precipitating adrenal insufficiency. The overnight metyrapone test is most useful in patients with partial secondary adrenal insufficiency in whom the rapid ACTH stimulation test is normal or borderline. It has been shown to correlate well with the response to insulin-induced hypoglycemia. .

C. CRH stimulation   Ovine CRH administered intravenously is used to assess ACTH secretory dynamics. In healthy subjects, CRH (1 µg/kg) provokes a peak ACTH response within 15 minutes and a peak cortisol response within 30 to 60 minutes. This dose may be associated with mild flushing, occasional shortness of breath, tachycardia, and hypotension. Patients with primary adrenal insufficiency have elevated basal ACTH levels and exaggerated ACTH responses to CRH. Secondary adrenal insufficiency results in an absent ACTH response to CRH in patients with pituitary corticotroph destruction; however, in patients with hypothalamic dysfunction, there is a prolonged and augmented ACTH response to CRH with a delayed peak. Since there are few data available on the ACTH and cortisol responses to CRH in normal subjects compared to those with secondary adrenal insufficiency, this study may have limitations.

ACTH Hypersecretion

ACTH hypersecretion is manifested by adrenocortical hyperfunction (Cushing syndrome). The diagnosis and differential diagnosis of ACTH hypersecretion and hypercortisolism are outlined in a later section on Cushing disease and also in Chapter 9. The low-dose dexamethasone suppression test is used to establish the presence of hypercortisolism regardless of its cause. Dexamethasone 1 mg is taken orally between 11 PM and midnight. The following morning at 8 AM, a blood sample is obtained for cortisol (and dexamethasone level if available or cortisol does not suppress). Cortisol values less than 1.8 µg/dL are normal. Sensitivity using this cutoff is good though specificity is compromised. Patient compliance, individual differences in dexamethasone metabolism, drugs that affect metabolism of dexamethasone, and medical conditions that alter cortisol secretion (acute illness, anxiety, depression, alcoholism) may influence the accuracy of this test.

EVALUATION OF GROWTH HORMONE

The evaluation of GH secretory reserve is important in the assessment of children with short stature and in adults with suspected hypopituitarism. Provocative tests are necessary because basal levels of GH are usually low and, therefore, do not distinguish between normal and GH-deficient patients. Special attention must be given to the methodology and the laboratory standards of GH measurement. Newer immunoassays give results that are 30% to 50% lower than older radioimmunoassays.

Insulin-Induced Hypoglycemia

The most reliable stimulus of GH secretion is insulin-induced hypoglycemia. In normal individuals, GH levels increase to more than 5 ng/mL after adequate hypoglycemia is achieved. Because 10% of normal individuals fail to respond to hypoglycemia, other stimulatory tests may be necessary.

GHRH-Arginine Test

Both forms of human GHRH (GHRH-40 and GHRH-44) have been used to evaluate GH secretory capacity. A dose of GHRH (1 µg/kg) combined with a 30-minute infusion of arginine (0.5 g/kg to a maximum of 20 g), which presumably reduces hypothalamic somatostatin secretion, promptly stimulates GH; the mean peak is 10 to 15 ng/mL (460-700 pmol/L) at 30 to 60 minutes in healthy subjects. The results are comparable to those achieved with insulin-induced hypoglycemia. Unfortunately, GHRH is no longer available in the United States.

Glucagon Stimulation Test

Glucagon can also be used to evaluate GH secretory capacity. A dose of glucagon (1 mg) is given intramuscularly, and GH levels are measured every 30 minutes for 3 to 4 hours. In adults with GH deficiency, peak GH levels fail to rise above 3 ng/mL.

Tests with Levodopa, Arginine, and Other Stimuli

Stimulation testing with levodopa, arginine infusion alone, or propranolol, is less reliable in the diagnosis of GH deficiency.

GH Hypersecretion

The evaluation of GH hypersecretion is discussed in the section on acromegaly and is most conveniently assessed by GH suppression testing with oral glucose and measurement of IGF-1 levels.

EVALUATION OF PROLACTIN

PRL secretion by the pituitary is resistant to local damage; decreased PRL secretory reserve indicates severe intrinsic pituitary disease.

PRL hypersecretion is a common endocrine problem. Macroprolactinemia can be assessed using polyethylene glycol precipitation of serum samples. Additional evaluation of hyperprolactinemia is discussed in the section on prolactinomas.

EVALUATION OF THYROID-STIMULATING HORMONE

Basal Measurements

The laboratory evaluation of TSH secretory reserve begins with an assessment of target gland secretion; thyroid function tests (free

thyroxine [FT_4]) should be obtained. Normal thyroid function studies in a clinically euthyroid patient indicate adequate TSH secretion, and no further studies are warranted. Laboratory evidence of hypothyroidism requires measurement of a TSH level. With primary thyroid gland failure, the TSH level is elevated; low or normal TSH in the presence of hypothyroidism suggests hypothalamic-pituitary dysfunction (see Chapter 7).

TRH Test

Because accurate methods for determining TSH and FT_4 readily establish the diagnosis of hypothyroidism in virtually all patients, the TRH test is rarely indicated today (TRH [protirelin] is also not currently commercially available).

EVALUATION OF LH AND FSH

Testosterone and Estrogen Levels

The evaluation of gonadotropin function also requires assessment of target gland secretory function, and measurement of gonadal steroids (testosterone in men, estradiol in women) is useful in the diagnosis of hypogonadism. In women, the presence of regular menstrual cycles is strong evidence that the hypothalamic-pituitary-gonadal axis is intact. Estradiol levels rarely fall below 50 pg/mL (180 pmol/L), even during the early follicular phase. A level of less than 30 pg/mL (110 pmol/L) in the presence of oligomenorrhea or amenorrhea is indicative of gonadal failure. In men, serum testosterone (normal range, 300-1000 ng/dL; 10-35 nmol/L) is a sensitive index of gonadal function (see Chapters 12 and 13).

LH and FSH Levels

In the presence of gonadal insufficiency, high LH and FSH levels are a sign of primary gonadal failure; low or normal LH and FSH suggest hypothalamic-pituitary dysfunction (hypogonadotropic hypogonadism).

GnRH Test

LH and FSH secretory reserves may be assessed with the use of synthetic GnRH (gonadorelin). Administration of GnRH causes a prompt increase in plasma LH and a lesser and slower increase in FSH. However, in most patients, the GnRH test provides no more useful information than is obtained by measurement of basal gonadotropin and gonadal steroid levels. Thus, this test is uncommonly performed. (GnRH is also not commercially available in the United States.)

PROBLEMS IN EVALUATION OF THE HYPOTHALAMIC-PITUITARY AXIS

This section briefly outlines some of the disorders and conditions that may cause confusion and lead to misinterpretation of pituitary function tests. The effects of drugs are described in the next section.

Obesity

GH dynamics are impaired in many severely obese patients; all provocative stimuli, including insulin-induced hypoglycemia, arginine, levodopa, and glucagon plus propranolol, often fail to provoke GH secretion. The GH response to GHRH is also impaired in obesity and improves with weight loss. Obesity is also a common cause of hypogonadotropic hypogonadism in adult men.

Diabetes Mellitus

Although glucose normally suppresses GH secretion, most individuals with type 1 diabetes have normal or elevated GH levels that often do not rise further in response to hypoglycemia or arginine. Levodopa increases GH in some diabetic patients, and even a dopamine infusion (which produces no GH change in nondiabetic subjects, because it does not cross the blood–brain barrier), stimulates GH in diabetic patients. Despite the increased GH secretion in patients with inadequately controlled diabetes, the GH response to GHRH in insulin-dependent diabetic patients is similar to that of nondiabetic subjects. IGF-1 levels are low in insulin-deficient diabetes despite the elevated GH levels.

Uremia

Basal levels of GH, PRL, LH, FSH, TSH, and free cortisol tend to be elevated, for the most part owing to prolongation of their plasma half-life. GH may paradoxically increase following glucose administration and is often hyperresponsive to a hypoglycemic stimulus. Although the administration of TRH has no effect on GH secretion in healthy subjects, the drug may increase GH in patients with chronic renal failure. The response of PRL to TRH is blunted and prolonged. Gonadotropin response to synthetic GnRH usually remains intact. Dexamethasone suppression of cortisol may be impaired.

Starvation and Anorexia Nervosa

GH secretion increases with fasting and malnutrition, and such conditions may cause a paradoxical increase in GH following glucose administration. Severe starvation, such as occurs in patients with anorexia nervosa, may result in low levels of gonadal steroids. LH and FSH responses to GnRH may be intact despite a state of functional hypogonadotropic hypogonadism. Cortisol levels are frequently increased and fail to suppress adequately with dexamethasone. PRL and TSH dynamics are usually normal despite a marked decrease in circulating total thyroid hormones (see Chapter 7).

Depression

Depression may alter the ability of dexamethasone to suppress plasma cortisol and may elevate cortisol secretion; the response to insulin-induced hypoglycemia usually remains intact. In addition, late-evening salivary cortisol levels usually remain normal and are not elevated as seen in patients with Cushing syndrome. The ACTH response to CRH is blunted in endogenous depression. Some depressed patients also have abnormal GH dynamics: TRH may increase GH, and hypoglycemia or levodopa may fail to increase GH. These patients may also show blunted TSH responses to TRH.

Pharmacologic Agents and Alcohol

Glucocorticoid excess impairs the GH response to hypoglycemia, the TSH response to TRH, and the LH response to GnRH. Estrogens tend to augment GH dynamics as well as the PRL and TSH response to TRH. Estrogens increase plasma cortisol secondary to a rise in corticosteroid-binding globulin and may result in inadequate suppression with dexamethasone.

Phenytoin enhances the metabolism of dexamethasone, making clinical testing in patients of this agent difficult to interpret. Phenothiazines may blunt the GH response to hypoglycemia and levodopa and frequently cause hyperprolactinemia. The many other pharmacologic agents that increase PRL secretion are listed in Table 4–8.

Narcotics, including heroin, morphine, and methadone, may all raise PRL levels and suppress GH and cortisol response to hypoglycemia. Opioids will also suppress hypothalamic CRH and thereby decrease ACTH and cortisol secretion. Hypogonadism is common with narcotic use.

In chronic alcoholics, alcohol excess or withdrawal may increase cortisol levels and cause inadequate dexamethasone suppression and an impaired cortisol increase after hypoglycemia.

ENDOCRINE TESTS OF HYPOTHALAMIC-PITUITARY FUNCTION

Protocols for performing endocrine tests and their normal responses are summarized in Table 4–9. The indications for and the clinical utility of these procedures are described in the preceding section and will be mentioned again in the section on pituitary and hypothalamic disorders.

NEURORADIOLOGIC EVALUATION

Symptoms of pituitary hormone excess or deficiency, headache, or visual disturbance lead the clinician to consider a hypothalamic-pituitary disorder. In this setting, accurate neuroradiologic assessment of the hypothalamus and pituitary is essential in confirming the existence and defining the extent of hypothalamic-pituitary lesions. However, the diagnosis of such lesions should be based on both endocrine and radiologic criteria, because variability of pituitary anatomy in the normal population may lead to false-positive interpretations. Furthermore, patients with pituitary microadenomas may have normal neuroradiologic studies. Imaging studies must be interpreted in light of the fact that 10% to 20% of the general population harbor nonfunctional and asymptomatic pituitary microadenomas.

Magnetic Resonance Imaging (MRI)

MRI is the current procedure of choice for imaging the hypothalamus and pituitary. It has superseded the use of computed tomography (CT) because it allows better definition of normal structures and has better resolution in defining tumors. Arteriography is rarely utilized at present except in patients with intrasellar or parasellar aneurysms.

Imaging is performed in sagittal and coronal planes at 1.5 to 2 mm intervals. This allows clear definition of hypothalamic and pituitary anatomy and accurately visualize lesions as small as 3 to 5 mm. The use of the heavy-metal contrast agent gadolinium allows even more precise differentiation of small pituitary adenomas from normal anterior pituitary tissue and other adjacent structures as shown in Figure 4–16.

A. Normal anatomy The normal anterior pituitary is 5 to 7 mm in height and approximately 10 mm in its lateral dimensions. The superior margin is flat or concave but may be upwardly convex with a height of 10 to 12 mm in healthy menstruating young women. The floor of the sella turcica is formed by the bony roof of the sphenoid sinus, and its lateral margins are formed by the dural membranes of the cavernous sinuses, which contain the carotid arteries and the third, fourth, and sixth cranial nerves. The posterior pituitary appears on MRI as a high-signal-intensity structure, the "posterior pituitary bright spot," which is absent in patients with diabetes insipidus. The pituitary stalk, which is normally in the midline, is 2 to 3 mm in diameter and 5 to 7 mm in length. The pituitary stalk joins the inferior hypothalamus below the third ventricle and posterior to the optic chiasm. All of these normal structures are readily visualized with MRI; the normal pituitary
FIGURE 4–16 **Upper panel: A**: The coronal magnetic resonance (MR) image shows a large nonfunctioning pituitary adenoma (arrows) with pronounced suprasellar extension and chiasmal compression. **B**: A sagittal MR image of another large pituitary adenoma shows spontaneous hemorrhage within the suprasellar portion of the adenoma (arrows). **Lower panel**: Gadolinium-enhanced MR images are shown of the pituitary gland. **A and B**: Coronal and sagittal images show the normal, uniformly enhancing pituitary stalk and pituitary gland. **C**: A pituitary microadenoma appears as a low-intensity lesion in the inferior aspect of the right lobe of the gland (arrow). **D**: The pituitary microadenoma appears as a low-intensity lesion between the left lobe of the pituitary and the left cavernous sinus (arrow). (Used with permission from David Norman, MD.)

and the pituitary stalk show increased signal intensity with gadolinium.

B. Microadenomas   These lesions, which range from 2 to 10 mm in diameter, appear as low-signal-intensity lesions on MRI and do not usually enhance with gadolinium. Adenomas less than 5 mm in diameter may not be visualized and do not usually alter the normal pituitary contour. Lesions greater than 5 mm in diameter create a unilateral convex superior gland margin and usually cause deviation of the pituitary stalk toward the side opposite the adenoma.

MRI scans must be interpreted with caution, because minor abnormalities occur in 10% of patients who have had incidental high-resolution scans but no clinical pituitary disease. These abnormalities may represent the clinically insignificant pituitary abnormalities that occur in 10% to 20% of the general population, and they may also be due to small intrapituitary cysts, which usually occur in the pars intermedia. Artifacts within the sella turcica associated with the bones of the skull base may also result in misinterpretation of imaging studies. Finally, many patients with pituitary microadenomas have normal high-resolution MRI scans. Therefore, despite increased accuracy of neuroradiologic diagnosis, the presence or absence of a small pituitary tumor and the decision concerning its treatment must be based on the entire clinical picture.

C. Macroadenomas   Pituitary adenomas greater than 10 mm in diameter are readily visualized with MRI scans, and the scan also defines the adjacent structures and degree of extension of the lesion. Thus, larger tumors show compression of the normal pituitary and distortion of the pituitary stalk. Adenomas larger than 1.5 cm frequently have suprasellar extension, and MRI scans show compression and upward displacement of the optic chiasm. Less commonly, there is lateral extension and invasion of the cavernous sinus.

D. Other uses   High-resolution MRI scanning is also a valuable tool in the diagnosis of empty sella syndrome, hypothalamic tumors, and other parasellar lesions.

PITUITARY AND HYPOTHALAMIC DISORDERS

Hypothalamic-pituitary lesions present with a variety of manifestations, including pituitary hormone hypersecretion and hyposecretion, sellar enlargement, headache, and visual loss. The approach to evaluation should be designed to ensure early diagnosis at a stage when the lesions are amenable to therapy.

Etiology and Early Manifestations

In adults, the most common cause of hypothalamic-pituitary dysfunction is a pituitary adenoma. Some of the earliest symptoms of pituitary tumors are due to endocrinologic abnormalities. These usually precede sellar enlargement and local manifestations such as

headache and visual loss which are late manifestations seen in patients with larger tumors or suprasellar extension.

In children, pituitary adenomas are uncommon; the most frequent structural lesions causing hypothalamic-pituitary dysfunction are craniopharyngiomas and other hypothalamic tumors. These also usually manifest as endocrine disturbances (low GH levels, delayed puberty, diabetes insipidus) prior to the development of headache, visual loss, or other central nervous system symptoms.

Common and Later Manifestations

A. Pituitary hypersecretion   PRL is the hormone most commonly secreted in excess amounts by pituitary adenomas, and it is usually elevated in patients with hypothalamic disorders and pituitary stalk compression as well. Thus, PRL measurement is essential in evaluating patients with suspected pituitary disorders and should be performed in patients presenting with galactorrhea, gonadal dysfunction, secondary gonadotropin deficiency, or enlargement of the sella turcica. Hypersecretion of GH or ACTH leads to the more characteristic syndromes of acromegaly and Cushing disease, respectively (see discussion later).

B. Pituitary insufficiency   Although panhypopituitarism is a classic manifestation of pituitary adenomas, it is present in less than 20% of patients in current large series because of earlier diagnosis of these lesions.

The earliest clinical manifestation of a pituitary adenoma in adults is hypogonadism secondary to elevated levels of PRL, GH, or ACTH and cortisol. The hypogonadism in these patients is due to interference with the secretion of GnRH rather than to destruction of anterior pituitary tissue. Thus, patients with hypogonadism should first be screened with FSH and LH measurements to exclude primary gonadal failure (elevated FSH or LH) and those with hypogonadotropic hypogonadism should have serum PRL levels measured and be examined for clinical evidence of GH or ACTH and cortisol excess.

In children, short stature is the most frequent clinical presentation of hypothalamic-pituitary dysfunction; in these patients, GH deficiency should be considered (see Chapter 6).

TSH or ACTH deficiency is relatively unusual and, if present, usually indicates panhypopituitarism. Thus, patients with secondary hypothyroidism or hypoadrenalism should undergo a complete assessment of pituitary function and neuroradiologic studies, because panhypopituitarism and large pituitary tumors are common in this setting. PRL measurement is again essential, because prolactinomas are the most frequent pituitary tumors in adults.

C. Enlarged sella turcica   Patients may present with enlargement of the sella turcica, which may be noted on radiographs performed for head trauma or on sinus series. These patients usually have either a pituitary adenoma or empty sella syndrome. Other less common causes include craniopharyngioma, lymphocytic hypophysitis, and carotid artery aneurysm. Evaluation should include clinical assessment of pituitary dysfunction and measurements of PRL and thyroid and adrenal function. Pituitary

function is usually normal in the empty sella syndrome; this diagnosis can be confirmed by MRI. Patients with clinical or laboratory evidence of pituitary dysfunction usually have a pituitary adenoma.

D. Visual field defects   Patients presenting with bitemporal hemianopsia or unexplained visual field defects or visual loss should be considered to have a pituitary or hypothalamic disorder until proven otherwise. The initial steps in diagnosis should be neuro-ophthalmologic evaluation and neuroradiologic studies with MRI, which will reveal the tumor if one is present. These patients should also have PRL measurements and be assessed for anterior pituitary insufficiency, which is especially common with large pituitary adenomas.

In addition to causing visual field defects, large pituitary lesions may extend laterally into the cavernous sinus, compromising the function of the third, fourth, or sixth cranial nerve, leading to diplopia.

E. Diabetes insipidus   Diabetes insipidus is a common manifestation of hypothalamic lesions and metastases to the pituitary, but simply never occurs in primary pituitary lesions. Diagnostic evaluation is described in Chapter 5. In addition, all patients should undergo radiologic evaluation and assessment of anterior pituitary function.

EMPTY SELLA SYNDROME

Etiology and Incidence

Empty sella syndrome occurs when the subarachnoid space extends into the sella turcica, partially filling it with cerebrospinal fluid. This process causes remodeling and enlargement of the sella turcica and flattening of the pituitary gland.

Primary empty sella syndrome resulting from congenital incompetence of the diaphragma sellae (Figure 4–17) is common, with an incidence in autopsy series ranging from 5% to 23%. It is the most frequent cause of enlarged sella turcica. An empty sella is also commonly seen after pituitary surgery or radiation therapy and may also occur following postpartum pituitary infarction (Sheehan syndrome). In addition, both PRL-secreting and GH-secreting pituitary adenomas may undergo subclinical hemorrhagic infarction and cause contraction of the overlying suprasellar cistern downward into the sella. Therefore, the presence of an empty sella does not exclude the possibility of a coexisting pituitary tumor.

Clinical Features

A. Symptoms and signs   Most patients are middle-aged obese women. Many have systemic hypertension; benign intracranial hypertension may also occur. Although 48% of patients complain of headache, this feature may have only initiated the evaluation (ie, imaging of the brain/head), and its relationship to the empty sella is probably coincidental. Serious clinical manifestations are uncommon. Spontaneous cerebrospinal fluid rhinorrhea and visual field impairment may occur rarely.

B. Laboratory findings   Tests of anterior pituitary function are almost always normal, although some patients have hyperprolactinemia. Endocrine function studies should be performed to exclude pituitary hormone insufficiency or a hypersecretory pituitary microadenoma.

Diagnosis

The diagnosis of empty sella syndrome can be readily confirmed by MRI, which demonstrates the herniation of the diaphragma sellae and the presence of cerebrospinal fluid in the sella turcica.
FIGURE 4–17 Representation of the normal relationship of the meninges to the pituitary gland **(left)** and the findings in the empty sella **(right)** as the arachnoid membrane herniates through the incompetent diaphragma sellae. (Reproduced with permission from Jordan RM, Kendall JW, Kerber CW. The primary empty sella syndrome: analysis of the clinical characteristics, radiographic features, pituitary function, and cerebrospinal fluid adenohypophysial hormone concentrations. *Am J Med*. 1977 Apr;62(4):569-580.)

HYPOTHALAMIC DYSFUNCTION

Hypothalamic dysfunction is most often caused by tumors, of which craniopharyngioma is the most common in children, adolescents, and young adults. In older adults, primary central nervous system tumors and those arising from hypothalamic (epidermoid and dermoid tumors) and pineal structures (pinealomas) are more common. Other causes of hypothalamic-pituitary dysfunction are discussed later in the section on hypopituitarism.

Clinical Features

A. Craniopharyngioma   Craniopharyngiomas are thought to originate from metaplasia of remnant epithelial cell rests in Rathke pouch and the craniopharyngeal duct during development. They are classified as adamantinomatous or papillary. Most adamantinomatous tumors have mutations in the beta-catenin gene while BRAF mutations have been found in papillary craniopharyngiomas. The differential diagnosis includes Rathke cleft cysts and arachnoid cysts. Rathke cleft cysts are a common incidental finding within the pituitary, but may present with symptoms similar to craniopharyngiomas. Although Rathke cleft cysts and craniopharyngiomas are both thought to arise from Rathke pouch during development, craniopharyngiomas tend to be more aggressive and are more likely to recur after resection.

The initial symptoms of craniopharyngioma in children and adolescents are predominantly endocrinologic; however, these manifestations are frequently unrecognized, and at diagnosis more than 80% of patients have hypothalamic-pituitary endocrine deficiencies. These endocrine abnormalities may precede presenting symptoms by months or years; GH deficiency is most common, with about 50% of patients having growth retardation and approximately 70% decreased GH responses to stimulation at diagnosis. Gonadotropin deficiency leading to absent or arrested puberty is usual in older children and adolescents; TSH and ACTH deficiencies are less common, and diabetes insipidus is present in about 15%.

Symptoms leading to the diagnosis are frequently neurologic and due to the mass effect of the expanding tumor. Symptoms of increased intracranial pressure such as headache and vomiting are present in about 40% of patients; decreased visual acuity or visual field defects are the presenting symptoms in another 35%. MRI confirms the tumor in virtually all patients; in 95%, the tumor is suprasellar.

In adults, craniopharyngiomas have similar presentations; that is, the diagnosis is usually reached as a result of investigation of complaints of headache or visual loss. However, endocrine manifestations—especially hypogonadism, diabetes insipidus, or other deficiencies of anterior pituitary hormones—usually precede these late manifestations. MRI readily demonstrates the tumors, which in adults are almost always both intrasellar and suprasellar. The appearance is typically of a heterogeneous, cystic mass that enhances with contrast. Calcifications may also be present.

B. Other tumors   Other hypothalamic or pineal tumors and primary central nervous system tumors involving the hypothalamus have variable presentations in both children and adults. Thus, presentation is with headache, visual loss, symptoms of increased intracranial pressure, growth failure, various degrees of hypopituitarism, or diabetes insipidus. Endocrine deficiencies usually precede neurologic manifestations. Hypothalamic tumors in childhood may present with precocious puberty.

C. Other manifestations of hypothalamic dysfunction
Lesions in the hypothalamus can cause many other abnormalities, including disorders of consciousness, behavior, thirst, appetite, and temperature regulation. These abnormalities are usually accompanied by hypopituitarism and diabetes insipidus.

Somnolence can occur with hypothalamic lesions, as can a variety of changes in emotional behavior. Decreased or absent thirst may occur and predispose these patients to dehydration. When diminished thirst accompanies diabetes insipidus, fluid balance is difficult to control. Hypothalamic dysfunction may also cause increased thirst, leading to polydipsia and polyuria that may mimic diabetes insipidus. Obesity is common in patients with hypothalamic tumors because of hyperphagia, decreased satiety, and decreased activity. Frohlich syndrome, or adiposogenital dystrophy, is characterized by obesity, growth retardation, and delayed development of sexual organs. Anorexia and weight loss are unusual manifestations of these tumors.

Temperature regulation can also be disordered in these patients. Sustained or, less commonly, paroxysmal hyperthermia can occur following acute injury due to trauma, hemorrhage, or craniotomy. This problem usually lasts less than 2 weeks. Poikilothermia, the inability to adjust to changes in ambient temperature, can occur in patients with bilateral hypothalamic lesions. These patients most frequently exhibit hypothermia but can also develop hyperthermia during hot weather. A few patients manifest sustained hypothermia due to anterior hypothalamic lesions.

Diagnosis

Patients with suspected hypothalamic tumors should undergo MRI to determine the extent and nature of the tumor. Complete assessment of anterior pituitary function is necessary in these patients, because deficiencies are present in the great majority (see section on Hypopituitarism later), and the evaluation will establish the requirements for replacement therapy. PRL levels should also be determined, because most hypothalamic lesions cause hyperprolactinemia either by hypothalamic injury or by damage to the pituitary stalk.

Treatment

Treatment depends on the type of tumor. Complete resection of craniopharyngioma is usually not feasible, and neurologic complications can be devastating with aggressive intervention. Therefore, this tumor is best managed by observation and replacement of insufficient hormones, or limited neurosurgical removal of accessible tumor and decompression of cysts, possibly followed by radiotherapy. Patients treated by this method have a recurrence rate of approximately 20%; with surgery alone, the recurrence rate approximates 80%.

Other hypothalamic tumors are usually not completely resectable; however, biopsy is indicated to arrive at a histologic diagnosis.

HYPOPITUITARISM

Hypopituitarism is manifested by diminished or absent secretion of one or more pituitary hormones. The development of signs and symptoms is often slow and insidious, depending on the rate of onset and the magnitude of hypothalamic-pituitary damage—factors that are influenced by the underlying pathogenesis. Hypopituitarism is either a primary event caused by destruction of the anterior pituitary gland or a secondary phenomenon resulting from deficiency of hypothalamic stimulatory factors normally acting on the pituitary. In general, acquired loss of anterior pituitary function follows the sequence of GH, LH/FSH, TSH, ACTH, and PRL. Treatment and prognosis depend on the extent of hypofunction, the underlying cause, and the location of the lesion in the hypothalamic-pituitary axis.

Etiology

The etiologic considerations in hypopituitarism are diverse. As shown later, a helpful mnemonic device is the phrase "nine Is": invasive, infarction, infiltrative, injury, immunologic, iatrogenic, infectious, idiopathic, and isolated. Most of these lesions may cause pituitary or hypothalamic failure (or both). Establishing the precise cause of hypopituitarism is helpful in determining treatment and prognosis.

A. Invasive   Space-occupying lesions cause hypopituitarism by destroying the pituitary gland or hypothalamic nuclei or by disrupting the hypothalamic-hypophysial portal venous system. Large pituitary adenomas cause hypopituitarism by these mechanisms, and pituitary function may improve after their removal. Small pituitary tumors—microadenomas (<10 mm in diameter)—characteristically seen in the hypersecretory states (excess PRL, GH, ACTH) do not directly cause pituitary insufficiency. Craniopharyngioma, the most common tumor of the hypothalamic-pituitary region in children, frequently impairs pituitary function by its compressive effects. Primary central nervous system tumors, including meningioma, chordoma, optic glioma, epidermoid tumors, and dermoid tumors, may decrease hypothalamic-pituitary secretion by their mass effects. Metastatic lesions to this area are common (especially breast carcinoma) but rarely result in clinically obvious hypopituitarism. Anatomic malformations such as basal encephalocele and parasellar aneurysms cause hypothalamic-pituitary dysfunction and may enlarge the sella turcica and mimic pituitary tumors.

B. Infarction   Ischemic damage to the pituitary has long been recognized as a cause of hypopituitarism. In 1914, Simmonds reported pituitary necrosis in a woman with severe puerperal sepsis. In 1937 Sheehan published his classic description of its occurrence following postpartum hemorrhage and vascular collapse.

The mechanism for the ischemia in such cases is not certain. Hypotension along with vasospasm of the hypophysial arteries is currently believed to compromise arterial perfusion of the anterior pituitary. During pregnancy, the pituitary gland may be more sensitive to hypoxemia because of its increased metabolic needs or more susceptible to the prothrombotic effects of the hyperestrogenic state. Some investigators have noted that the hypopituitarism does not always correlate with the degree of hemorrhage but that there is good correlation between the pituitary lesion and severe disturbances of the clotting mechanism (as in patients with placenta previa). Ischemic pituitary necrosis has also been reported to occur with greater frequency in patients with diabetes mellitus.

The extent of pituitary damage determines the rapidity of onset as well as the magnitude of pituitary hypofunction. The gland has a great secretory reserve, and more than 75% must be destroyed before clinical manifestations are evident. The initial clinical feature in postpartum necrosis may be failure to lactate after parturition; failure to resume normal menstrual periods is another clue to the diagnosis. However, the clinical features of hypopituitarism are often subtle, and years may pass before pituitary insufficiency is recognized following an ischemic insult.

Spontaneous hemorrhagic infarction of a pituitary tumor (pituitary apoplexy) frequently results in partial or total pituitary insufficiency. Pituitary apoplexy is often a fulminant clinical syndrome manifested by severe headache, visual impairment, ophthalmoplegias, meningismus, and an altered level of consciousness. Pituitary apoplexy is usually associated with a pituitary tumor; it may also be related to diabetes mellitus, radiotherapy, or open heart surgery. Acute pituitary failure with hypotension may result, and rapid mental deterioration, coma, and death may ensue. Emergency treatment with corticosteroids (see Chapter 24) and transsphenoidal decompression of the intrasellar contents may be lifesaving and may prevent permanent visual loss. Most patients who have survived pituitary apoplexy have developed multiple adenohypophysial deficits, but infarction of the tumor in some patients may cure the hypersecretory pituitary adenoma and its accompanying endocrinopathy. Pituitary infarction may also be a subclinical event (silent pituitary apoplexy), resulting in improvement of pituitary hormone hypersecretion without impairing the secretion of other anterior pituitary hormones.

C. Infiltrative   Hypopituitarism may be the initial clinical manifestation of infiltrative disease processes such as sarcoidosis, hemochromatosis, and Langerhan histiocytosis.

1. **Sarcoidosis**—The most common intracranial sites of involvement of sarcoidosis are the hypothalamus and pituitary gland. At one time, the most common endocrine abnormality in patients with sarcoidosis was thought to be diabetes insipidus; however, many of these patients actually have centrally mediated disordered control of thirst that results in polydipsia and polyuria, which in some cases explains the abnormal water metabolism. Deficiencies of multiple anterior pituitary hormones have been well documented in sarcoidosis and are usually secondary to hypothalamic insufficiency. Granulomatous involvement of the hypothalamic-pituitary unit is occasionally

extensive, resulting in visual impairment, and therefore, may simulate the clinical presentation of a pituitary or hypothalamic tumor.

2. **Hemochromatosis**—Hypopituitarism, particularly hypogonadotropic hypogonadism, is a prominent manifestation of iron storage disease—either primary (hereditary) hemochromatosis or transfusional iron overload. Hypogonadism occurs in most such cases and is often the initial clinical feature of iron excess; complete iron studies should be considered in any patient presenting with unexplained hypogonadotropic hypogonadism. If the diagnosis is established early, hypogonadism in hemochromatosis may be reversible with iron depletion. Pituitary deficiencies of TSH, GH, and ACTH may occur later in the course of the disease and are not reversible by iron chelation therapy.

3. **Langerhan histiocytosis**—In this disorder, the infiltration of multiple organs by well-differentiated histiocytes, is often heralded by the onset of diabetes insipidus and anterior pituitary hormone deficiencies. Most histologic and biochemical studies have indicated that this infiltrative process involves chiefly the hypothalamus, and hypopituitarism occurs only as a result of hypothalamic damage.

D. Injury   Severe head trauma may cause anterior pituitary insufficiency and diabetes insipidus. Posttraumatic anterior hypopituitarism may be due to injury to the anterior pituitary, the pituitary stalk, or the hypothalamus. Pituitary insufficiency with growth retardation has been described in battered children who suffer closed head trauma with subdural hematoma.

E. Immunologic   Lymphocytic hypophysitis resulting in anterior hypopituitarism is a distinct entity, occurring most often in women during pregnancy or in the postpartum period. It may present as a mass lesion of the sella turcica with visual field disturbances simulating pituitary adenoma. An autoimmune process with extensive infiltration of the gland by lymphocytes and plasma cells destroys the anterior pituitary cells. These morphologic features are similar to those of other autoimmune endocrinopathies (eg, thyroiditis, adrenalitis, and oophoritis). About 50% of patients with lymphocytic hypophysitis have other endocrine autoimmune disease, and circulating pituitary autoantibodies have been found in several cases. It is presently uncertain how this disorder should be diagnosed and treated. It must be considered in the differential diagnosis of women with pituitary gland enlargement and hypopituitarism during pregnancy or the postpartum period. Hypophysitis may also be a component of immunoglobulin G4 (IgG4)-related systemic syndrome. In addition to findings of sellar mass and/or thickened pituitary stalk on MRI, many patients have elevated circulating IgG4 levels. Pathology of the pituitary lesion and other affected organs is characterized by a lymphoplasmacytic infiltrate enriched in IgG4-positive plasma cells. Most patients respond to glucocorticoid treatments.

Lymphocytic hypophysitis may result in isolated hormone deficiencies (especially ACTH or prolactin). Consequently, women with this type of hypopituitarism may continue to menstruate while suffering from secondary hypothyroidism or hypoadrenalism.

A newer class of medications, checkpoint inhibitors, have been associated with hypophysitis. Ipilimumab, an anti-neoplastic monoclonal antibody used to treat melanoma and other malignancies, has been shown to cause hypophysitis in 11% to 17% of patients in one review. Median time to diagnosis after initiation was 8 to 10 weeks. Most patients have pituitary enlargement, but visual defects are rare. Although pituitary enlargement resolves, hypopituitarism remains in most patients and ACTH deficiency may be the only anterior pituitary hormone deficit.

F. Iatrogenic   Both surgical and radiation therapy to the pituitary gland may compromise its function. The anterior pituitary is quite resilient during transsphenoidal microsurgery, and despite extensive manipulation during the search for microadenomas, anterior pituitary function is usually preserved. The dose of conventional radiation therapy presently employed to treat pituitary tumors is 4500 to 5000 cGy and results in a 50% to 60% incidence of hypothalamic and pituitary insufficiency. Such patients most frequently have modest hyperprolactinemia (PRL 30-100 ng/mL [1.3-4.5 nmol/L]) with GH and gonadotropin failure; TSH and ACTH deficiencies are less common. Heavy particle (proton beam) irradiation and gamma knife radiosurgery for pituitary tumors result in a 15% to 55% incidence of hypopituitarism. Irradiation of tumors of the head and neck (nasopharyngeal cancer, brain tumors) and prophylactic cranial irradiation in leukemia may also cause hypopituitarism. The clinical onset of pituitary failure in such patients is usually insidious and results from both pituitary and hypothalamic injury.

G. Infectious   Although many infectious diseases, including tuberculosis, syphilis, and mycotic infections, have been implicated as causative agents in pituitary hypofunction, antimicrobial drugs have now made them rare causes of hypopituitarism.

H. Idiopathic   In some patients with hypopituitarism, no underlying cause is found. These may be isolated (see discussion later) or multiple deficiencies. Familial forms of hypopituitarism characterized by a small, normal, or enlarged sella turcica have been described. Both autosomal recessive and X-linked recessive inheritance patterns have been reported. A variety of complex congenital disorders may include deficiency of one or more pituitary hormones (eg, Prader-Willi syndrome, septo-optic dysplasia). Although progress has been made into understanding the genetic basis for some of these disorders, the pathogenesis remains uncertain.

I. Isolated   Isolated (monotropic) deficiencies of the anterior pituitary hormones have been described. Some of these have been associated with mutations in the genes coding for the specific hormones. Others, particularly GH deficiency, have been associated with mutations in genes necessary for normal pituitary development as noted.

1. **GH deficiency**—In children, congenital monotropic GH deficiency may be sporadic or familial. These children, who may experience fasting hypoglycemia, have a gradual deceleration in

growth velocity after 6 to 12 months of age. Diagnosis must be based on failure of GH responsiveness to provocative stimuli and the demonstration of normal responsiveness of other anterior pituitary hormones. Monotropic GH deficiency and growth retardation have also been observed in children suffering severe emotional deprivation. This disorder is reversed by placing the child in a supportive psychosocial milieu. A more detailed description of GH deficiency and growth failure is provided in Chapter 6.

2. **ACTH deficiency**—Monotropic ACTH deficiency is rare and is manifested by the signs and symptoms of adrenocortical insufficiency. LPH deficiency has also been noted in such patients. The defect in these patients may be due to primary failure of the corticotrophs to release ACTH and its related peptide hormones or may be secondary to impaired secretion of CRH by the hypothalamus. Mutations in *Tpit* (T-box 19, a T-box factor only presents in POMC-expressing pituitary lineages) have been described in several patients with early onset isolated ACTH deficiency. Most acquired cases of monotropic ACTH deficiency are now due to checkpoint inhibitor immunotherapy.

3. **Gonadotropin deficiency**—Isolated deficiency of gonadotropins is not uncommon. Kallmann syndrome, initially described in the 1940s, is characterized by an isolated defect in GnRH secretion associated with maldevelopment of the olfactory center with hyposmia or anosmia; X-linked recessive, autosomal dominant, and autosomal recessive patterns of inheritance are seen. Sporadic cases occur, and other neurologic defects such as color blindness and nerve deafness have been reported. At least five Kallmann syndrome genes have been identified: *KAL1, FGFR1, FGF8, PROKR2*, and *PROK2. KAL1* mutations are responsible for the X-linked form of the disease and result in decreased expression of the extracellular glycoprotein anosmin-1. This, in turn, interferes with the normal embryonic development and migration of GnRH-secreting neurons. Because anterior pituitary function is otherwise intact, young men with isolated hypogonadotropic hypogonadism develop a eunuchoid appearance since testosterone deficiency results in failure of epiphysial closure (see Chapter 12). In women, a state of hypogonadotropic hypogonadism manifested by oligomenorrhea or amenorrhea often accompanies weight loss, emotional or physical stress, and athletic training. Anorexia nervosa and marked obesity both result in hypothalamic dysfunction and impaired gonadotropin secretion. Hypothalamic hypogonadism has also been observed in overtrained male athletes. Sickle cell anemia also causes hypogonadotropic hypogonadism due to hypothalamic dysfunction and results in delayed puberty. Clomiphene treatment has been effective in some cases. Isolated gonadotropin deficiency may also be seen in the polyglandular autoimmune syndrome; this deficiency is related to selective pituitary gonadotrope failure from autoimmune hypophysitis. Other chronic illnesses (eg, poorly controlled diabetes, malnutrition) may result in gonadotropin deficiency. Isolated deficiencies of both LH and FSH without an obvious cause such as those described have been reported but are rare. In addition, acquired partial gonadotropin deficiency may occur in middle-aged men. The cause and exact frequency of this disorder are unknown.

4. **TSH deficiency**—Monotropic TSH deficiency is rare and can be caused by a reduction in either hypothalamic TRH secretion (tertiary hypothyroidism) or pituitary TSH secretion (secondary hypothyroidism). These defects have reported in association with gene mutations, empty sella, lymphocytic hypophysitis, and pituitary tumors. Some patients with chronic renal failure also appear to have impaired TSH secretion.

5. **Prolactin deficiency**—PRL deficiency almost always indicates severe intrinsic pituitary damage, and panhypopituitarism is usually present. However, isolated PRL deficiency has been reported after lymphocytic hypophysitis. Deficiencies of TSH and PRL have been noted in patients with pseudohypoparathyroidism.

6. **Multiple hormone deficiencies isolated from other pituitary damage**—Multiple hormone deficiencies result from abnormal pituitary development related to abnormalities of the genes encoding the transcription factors, Pit-1 (TSH, GH, and PRL) and Prop-1 (TSH, GH, PRL, LH, FSH, and ACTH). Table 4–10 lists a number of other genes associated with multiple pituitary hormone deficiencies and hypoplasia including *NR0B1, Rpx, Lhx3, Lhx4*, and *Pitx2*.

Clinical Features

The onset of pituitary insufficiency is usually gradual, and the classic course of progressive hypopituitarism is an initial loss of GH and gonadotropin secretion followed by deficiencies of TSH, then ACTH, and finally PRL.

A. Symptoms   Impairment of GH secretion causes decreased growth in children but may be clinically occult in adult patients. GH deficiency is associated with a decreased sense of well-being and a lower health-related quality of life. Decreased muscle mass and increased fat mass can also be seen, although this may be difficult to discern in any given individual.

Hypogonadism, manifested by amenorrhea in women and decreased libido or erectile dysfunction in men, may antedate the clinical appearance of a hypothalamic-pituitary lesion. The only symptom of PRL deficiency is failure of postpartum lactation.

Hypothyroidism caused by TSH deficiency generally simulates the clinical changes observed in primary thyroid failure; however, it is usually less severe, and goiter is absent. Cold intolerance, dry skin, mental dullness, bradycardia, constipation, hoarseness, and anemia have all been observed; gross myxedematous changes are uncommon.

ACTH deficiency causes adrenocortical insufficiency, and its clinical features resemble those of primary adrenal failure. Weakness, nausea, vomiting, anorexia, weight loss, fever, and hypotension may occur. The zona glomerulosa and the renin-angiotensin system are usually intact; therefore, the dehydration and sodium depletion seen in Addison disease are uncommon. However, these patients are susceptible to hypotension, shock, and cardiovascular collapse, because glucocorticoids are necessary to maintain vascular reactivity, especially during stress. In addition, because of their gradual onset, the symptoms of secondary adrenal insufficiency may go undetected for prolonged periods, becoming manifest only during periods of stress. Hypoglycemia aggravated by GH deficiency may occur with fasting and has been the initial presenting feature of some patients with isolated ACTH deficiency. In contrast to the hyperpigmentation that occurs during states of ACTH excess (Addison disease, Nelson syndrome), depigmentation and diminished tanning have been described as a result of

TABLE 4–10 Genetics of pituitary tumors and pituitary insufficiency.

Pituitary adenomas			
Name	**Gene**	**Tumors/Hormone Excess**	**Function**
MEN1 syndrome	MEN1	Prolactinomas (ACTH, GH, non-functioning tumors less common)	Menin (tumor suppressor)
MEN4 syndrome	CDKN1B	Similar to MEN1	Cyclin-dependent kinase inhibitor 1B (p27, Kip1); important regulator of cell cycle progression, involved in G1 arrest and other functions
Familial isolated pituitary adenomas (familial acromegaly/gigantism)	AIP	GH secreting tumors	Aryl hydrocarbon receptor interacting protein (tumor suppressor)
McCune-Albright syndrome	GNAS1	GH hypersecretion	Adenylyl cyclase
Carney complex	PRKAR1A	GH hypersecretion	Loss of protein kinase A regulatory subunit-1 alpha activity (tumor suppressor)
X-linked acrogigantism (X-LAG)	GPR101	GH secreting tumors	Genomic duplication of Xq26.3
Cushing's disease	USP8	ACTH secreting tumors	Ubiquitin-specific protease 8 (deubiquitinase activity)
DICER1 syndrome	DICER-1	Pituitary blastoma	DICER-1 protein (RNA processing endoribonuclease)
Familial hyperprolactinemia	PRLR	Prolactin hypersecretion	Loss of function mutation in the prolactin receptor
Pituitary adenomas	PTTG1	All pituitary tumor subtypes	Pituitary tumor-transforming gene-1 (securin which regulates sister chromatid separation)
Other	CCND1 (Cyclin D1), H-ras, c-myc, Ptx	Pituitary adenomas/carcinomas	Activators of growth and cell cycle progression in pituitary cells.
Craniopharyngioma	CTNNB1	Adamantinomatous tumors	β-catenin protein, regulator of canonical Wnt signaling pathway
Craniopharyngioma	BRAF	Papillary tumors	B-Raf protein
Pituitary insufficiency			
Name	**Gene**	**Hormone Deficiency**	**Function**
X-linked congenital adrenal hypoplasia	NR0B1	Pituitary and hypothalamus (in addition to adrenals)	DAX-1 nuclear receptor protein (dosage-sensitive sex reversal, adrenal hypoplasia gene on the X chromosome, gene 1)
Early onset isolated ACTH deficiency	Tpit	ACTH deficiency	Transcription factor required for expression of the POMC gene
Kallmann syndrome	KAL1, FGFR1, FGF8, PROKR2, PROK2	GnRH deficiency (low FSH and LH)	Anosmin-1, fibroblast growth factor receptor 1, fibroblast growth factor-8, prokineticin receptor-2, prokineticin-2
Combined pituitary hormone insufficiency	Prop1	Multiple pituitary hormone deficiencies	Prop1 (Prophet of Pit1) protein is a transcription factor
Congenital hypopituitarism	POU1F1 (Pit1)	Multiple pituitary hormone deficiencies	Anterior pituitary transcription factor
Other	Rpx, Lhx3, Lhx4, Pitx2	Pituitary hypoplasia with pituitary hormone deficits	

ACTH insufficiency. In addition, lack of ACTH-stimulated adrenal androgen secretion will cause a decrease in body hair if gonadotropin deficiency is also present.

B. Signs   Abnormal findings on physical examination may be subtle and require careful observation. Patients with hypopituitarism are not cachectic. A photograph of a cachectic patient with "Simmonds syndrome" that appeared in some older textbooks of endocrinology caused confusion. That particular patient probably suffered from anorexia nervosa and was found to have a normal pituitary gland at postmortem examination.

Patients with hypopituitarism may have fine, pale, smooth skin and fine wrinkling of the face. Body and pubic hair may be deficient or absent, and atrophy of the genitalia may occur. Postural hypotension, bradycardia, decreased muscle strength, and delayed deep tendon reflexes occur in more severe cases. Neuro-ophthalmologic abnormalities depend on the presence of a large intrasellar or parasellar lesion.

C. Laboratory and other findings   These may include anemia (related to thyroid and androgen deficiency and chronic disease), hypoglycemia, hyponatremia (related to hypothyroidism and hypoadrenalism, which cause inappropriate water retention, not sodium loss), hypercalcemia (related to adrenal insufficiency with volume contraction and hemoconcentration), and low-voltage bradycardia on electrocardiographic testing. Hyperkalemia, which is common in primary adrenal failure, is

not present. Adult GH deficiency is associated with decreased red blood cell mass, increased LDL cholesterol, and decreased bone mass.

Diagnosis

A. Assessment of target gland function (Figure 4–18)   If endocrine hypofunction is suspected, pituitary hormone

FIGURE 4–18 Diagnostic evaluation of hypothalamic-pituitary-target gland hypofunction.

deficiencies must be distinguished from primary failure of the thyroid, adrenals, or gonads. Basal determinations of each anterior pituitary hormone are useful only if compared to target gland secretion. Baseline laboratory studies should include thyroid function tests (free T_4) and determination of serum testosterone levels. Testosterone is a sensitive indicator of hypopituitarism in women as well as in men. In women, a substantial decrease in testosterone is commonly observed in pituitary failure related to hypofunction of the two endocrine glands responsible for its production—the ovary and the adrenal. Adrenocortical reserve should initially be evaluated by a rapid ACTH stimulation test.

B. Evaluation of prolactin   Because hyperprolactinemia (discussed later), regardless of its cause, leads to gonadal dysfunction, serum PRL should be measured early in the evaluation of hypogonadism.

C. Differentiation of primary and secondary hypofunction
Subnormal thyroid function as shown by appropriate tests, a low serum testosterone level, or an impaired cortisol response to the rapid ACTH stimulation test requires measurement of basal levels of specific pituitary hormones. In primary target gland hypofunction, such as autoimmune polyglandular syndromes types 1 and 2 (APS 1 and 2), TSH, LH, FSH, or ACTH will be elevated. Low or normal values for these pituitary hormones suggest hypothalamic-pituitary dysfunction.

D. Stimulation tests   Provocative endocrine testing may then be employed to confirm the diagnosis and to assess the extent of hypofunction. At present, these tests are not required in most patients.

Treatment

A. ACTH   Treatment of secondary adrenal insufficiency, like that of primary adrenal failure, must include glucocorticoid support (see Chapter 9). Hydrocortisone (15-25 mg/d orally) or prednisone (5-7.5 mg/d orally) in two or three divided doses provides adequate glucocorticoid replacement for most patients. The minimum effective dosage should be given in order to avoid iatrogenic hypercortisolism. Increased dosage is required during periods of stress such as illness, surgery, or trauma. Patients with only partial ACTH deficiency may need steroid treatment only during stress. A two- to threefold increase in steroid dosage during the stressful situation should be recommended, followed by gradual tapering as the stress resolves. Unlike primary adrenal insufficiency, ACTH deficiency does not usually require mineralocorticoid therapy. Patients with adrenal insufficiency should wear medical alert bracelets so they may receive prompt treatment in case of emergency.

B. TSH   The management of patients with secondary hypothyroidism must be based on clinical grounds and the circulating concentration of serum thyroxine (see Chapter 7). The treatment of secondary and tertiary hypothyroidism is identical to that for primary thyroid failure. Full oral replacement dose of levothyroxine sodium is 1.6 µg/kg daily (0.1-0.15 mg/d is usually adequate). Response to therapy is monitored clinically and with measurement of serum-free thyroxine levels, which should be maintained in the mid to upper range of normal. Measurement of TSH levels is obviously of no value in the management of these patients.

Caution: Because thyroid hormone replacement in patients with hypopituitarism may aggravate even partial adrenal insufficiency, the adrenal hormone deficiency should be treated first.

C. Gonadotropins   The object of treatment of secondary hypogonadism is to replace sex steroids and restore fertility (see Chapters 12 and 13).

1. **Estrogens and progesterone**—In premenopausal women, estrogen replacement is essential. Adequate estrogen treatment maintains secondary sex characteristics (eg, vulvar and vaginal lubrication), prevents osteoporosis, and abolishes vasomotor symptoms, with an improvement in sense of well-being. Many estrogen preparations are available (eg, oral estradiol, 1-2 mg daily; conjugated estrogens, 0.3-1.25 mg orally daily; or transdermal estradiol, 0.05-0.1 mg daily). Estrogens should be cycled with a progestin compound (eg, medroxyprogesterone, 5-10 mg orally daily during the last 10 days of estrogen therapy each month) to induce withdrawal bleeding and prevent endometrial hyperplasia. Many oral contraceptive pill combinations are also clinically available.

2. **Ovulation induction**—Ovulation can often be restored in women with hypothalamic-pituitary dysfunction (see Chapter 13). In patients with gonadal failure of hypothalamic origin, clomiphene citrate may cause a surge of gonadotropin secretion resulting in ovulation. Pulsatile subcutaneous injections of GnRH with an infusion pump can also be used to induce ovulation and fertility in women with hypothalamic dysfunction. Combined treatment with FSH (human menopausal gonadotropins; menotropins) and LH (chorionic gonadotropin) can be utilized to provoke ovulation in women with intrinsic pituitary failure. This form of therapy is expensive, and multiple births are a risk (see Chapter 13).

3. **Androgens in women**—Because of a deficiency of both ovarian and adrenal androgens, some women with hypopituitarism have diminished libido despite adequate estrogen therapy. Although experience is limited, small doses of long-acting androgens (testosterone enanthate, 25-50 mg intramuscularly every 4-8 weeks) may be helpful in restoring sexual activity without causing hirsutism. In addition, some reports have suggested that oral dehydroepiandrosterone (DHEA) in doses of 25 to 50 mg/d may restore plasma testosterone levels to normal. A transdermal delivery system is being evaluated for use in women, but efficacy appears to be modest and the long-term safety is unknown.

4. **Androgens in men**—The treatment of male hypogonadism is discussed in Chapter 12. Testosterone gels (administered in doses of 10 to 120 mg daily depending on the concentration) are available in packets and metered-dose pumps. Testosterone patches (available as 2 and 4 mg) can be used in doses up to 6 mg daily. Other therapeutic preparations include intramuscular testosterone enanthate or cypionate in doses of 50 to 100 mg every week or 100 to 200 mg every 2 weeks.

Testosterone undecanoate is an intramuscular preparation (250 mg/mL) available in several countries that can be given every 3 months. Oral testosterone preparations available in the United States are rarely used out of concern for hepatic side effects.

5. **Spermatogenesis**—Spermatogenesis can be achieved in many patients with the combined use of hCG and recombinant FSH. If pituitary insufficiency is of recent onset, therapy with hCG alone may restore both fertility and adequate gonadal steroid production. Pulsatile GnRH infusion pumps have also been used to restore fertility in male patients with secondary hypogonadism.

D. Growth hormone (also see Chapter 6)   Human GH (hGH) produced by recombinant DNA technology is available for use in children with hypopituitarism and for adults with GH deficiency and known pituitary disease. Some studies indicate improvement in body composition, bone mineral density, psychologic well-being, and functional status with GH therapy. However, the long-term benefits and risks remain to be established. In adults, GH is usually administered subcutaneously, once per day in a dosage of 2 to 5 µg/kg. Monitoring of effectiveness is accomplished by measurement of IGF-1, and the dosage of GH is adjusted accordingly (up to about 10 µg/kg/d). Side effects (eg, edema, paresthesias, arrhythmias, glucose intolerance, diabetes) should be assessed. Contraindications to GH therapy include the presence of diabetic retinopathy, active malignancy, intracranial hypertension, radiotherapy, or airway obstruction in individuals with Prader-Willi syndrome.

PITUITARY ADENOMAS

Advances in endocrinologic and neuroradiologic research in recent years have allowed earlier recognition and more successful therapy of pituitary adenomas. In a population-based study, the distribution of each pituitary adenoma subtype was 57% for prolactinomas, 28% for nonfunctioning tumors, 11% for GH-secreting tumors, 2% for corticotroph adenomas, and 2% for unknown functional status. Hypersecretion of TSH, the gonadotropins, or alpha subunits is unusual, although the latter two may account for some of the "nonfunctional" tumors. The differential diagnosis of nonpituitary sellar and parasellar masses is listed in Table 4–11.

Early clinical recognition of the endocrine effects of excessive pituitary secretion, especially the observation that PRL excess causes secondary hypogonadism, has led to early diagnosis of pituitary tumors before the appearance of late manifestations, such as sellar enlargement, panhypopituitarism, and suprasellar extension with visual impairment.

Pituitary **microadenomas** are defined as intrasellar adenomas less than 1 cm in diameter that present with manifestations of hormonal excess without sellar enlargement or extrasellar extension. Panhypopituitarism does not occur, and such tumors can usually be treated successfully.

Pituitary **macroadenomas** are those larger than 1 cm in diameter and cause generalized sellar enlargement. Tumors 1 to 2 cm in diameter confined to the sella turcica can usually be successfully

treated; however, larger tumors—especially those with suprasellar, sphenoid sinus, or lateral extensions—are much more difficult to manage. Panhypopituitarism and visual loss increase in frequency with tumor size and suprasellar extension.

Insights into the pathogenesis and biologic behavior of pituitary tumors have been gained from studies of pituitary tumor clonality and somatic mutations. Analyses of allelic X inactivation of specific genes has shown that most pituitary adenomas are monoclonal, a finding most consistent with a somatic mutation model of tumorigenesis; polyclonality of tumors would be expected if tonic stimulation by hypothalamic-releasing factors were the mechanism underlying neoplastic transformation. In fact, transgenic animals expressing GHRH have exhibited pituitary hyperplasia but not pituitary adenomas. One somatic mutation has been found in 30% to 40% of GH-secreting tumors (but not in leukocytes from the same patients). Point mutations in the alpha subunit of the GTP-binding protein responsible for activation of adenylyl cyclase result in constitutive stimulation of pituitary cell growth and function. A host of other candidate genes have been described, including the pituitary tumor transforming gene (*PTTG1*). Overexpression of this gene has been found in all pituitary tumor types and may promote tumorigenesis through cell cycle disruption, stimulation of fibroblast growth factor secretion, and abnormal chromatid separation. Several genetic

syndromes are associated with pituitary tumors or pituitary hormone hypersecretion including multiple endocrine neoplasia (MEN) type 1, McCune-Albright syndrome, Carney complex, familial acromegaly/gigantism, and X-linked acrogigantism. Table 4–10 describes a number of known genetic causes of pituitary adenomas/hormone excess.

Treatment

Pituitary adenomas are treated with surgery, irradiation, or medications. The aims of therapy are to block effects of hormone excess, correct hypersecretion of anterior pituitary hormones, to preserve normal secretion of other anterior pituitary hormones, and to remove or suppress the adenoma itself. These objectives are currently achievable in most patients with pituitary microadenomas; however, in the case of larger tumors, multiple therapies are frequently required and may be less successful.

A. Surgical treatment   The transsphenoidal microsurgical approach to the sella turcica, now done endoscopically in most centers, is the procedure of choice; transfrontal craniotomy is required only in the rare patient with massive suprasellar extension of the adenoma. In the transsphenoidal procedure, the surgeon approaches the pituitary from the nasal cavity through the sphenoid sinus, removes the anterior-inferior sellar floor, and incises the dura. The adenoma is selectively removed; normal pituitary tissue is identified and preserved. Success rates approach 90% in patients with microadenomas. Major complications, including postoperative hemorrhage, cerebrospinal fluid leak, meningitis, and visual impairment, occur in less than 5% of patients and are most frequent in patients with large or massive tumors. Transient diabetes insipidus lasting a few days to 1 to 2 weeks occurs in approximately 15%; permanent diabetes insipidus is rare. A transient form of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) with symptomatic hyponatremia occurs in 10% of patients within 5 to 14 days of transsphenoidal pituitary microsurgery. These abnormalities of water balance can occur within days of each other making medical management difficult. A *triphasic response* of diabetes insipidus, SIADH, and diabetes insipidus is occasionally encountered and thought to be due to early hypothalamic dysfunction, followed by release of ADH from the degenerating pituitary, and then depletion of ADH stores. Surgical hypopituitarism is rare in patients with microadenomas but approaches 5% to 10% in patients with larger tumors. The perioperative management of such patients should include glucocorticoid administration in stress doses (see Chapter 9) and postoperative assessment of daily weight, fluid balance, and electrolyte status to look for evidence of diabetes insipidus. Mild diabetes insipidus is managed by giving fluids orally; in more severe cases—urine output greater than 5 to 6 L/24 h—ADH therapy in the form of desmopressin, or DDAVP, can be administered intranasally, orally, subcutaneously, or parenterally (see Chapter 5). SIADH is managed by fluid restriction; however, in more severe cases, hypertonic saline may be required. ADH receptor antagonists (tolvaptan is given orally and conivaptan is administered

intravenously) are also now available for use in some patients (see section on SIADH).

B. Radiotherapy   Pituitary irradiation should be reserved for patients who have had incomplete resection of larger pituitary adenomas and whose tumors are not amenable to, or have failed, medical therapy.

1. **Conventional irradiation**—Conventional irradiation using high-energy sources, in total doses of 4000 to 5000 cGy given in daily doses of 180 to 200 cGy, is most commonly employed. The response to radiation therapy is slow, and 5 to 10 years may be required to achieve the full effect (see section on Acromegaly). Treatment is ultimately successful in about 80% of patients with acromegaly but in only about 55% to 60% of patients with Cushing disease. The response rate in prolactinomas is not precisely known, but tumor progression is prevented in most patients. Morbidity during radiotherapy is minimal, although some patients experience malaise and nausea, and serous otitis media may occur. Hypopituitarism is common, and the incidence increases with time following radiotherapy—about 50% to 60% at 5 to 10 years. Rare late complications include damage to the optic nerves and chiasm, seizures, and radionecrosis of brain tissue. Recent studies from the United Kingdom have shown that conventional radiotherapy is a major risk factor for excess mortality in acromegaly.
2. **Gamma knife radiosurgery**—This form of radiotherapy utilizes stereotactic CT-guided cobalt-60 gamma radiation to deliver high-radiation doses to a narrowly focused area. Remission rates have been reported in the range of 43% to 78%. An adequate distance of the pituitary tumor from the optic chiasm is needed to prevent radiation-induced damage. Repeat treatments put patients at higher risk of new visual or third, fourth, or sixth cranial nerve deficits.
3. **Proton stereotactic radiotherapy**—Experience with this modality is limited. In one study, 52% of patients with Cushing disease had clinical remission. A similar rate of new pituitary hormone deficiencies was seen, although no visual complications or brain injury was reported.

C. Medical treatment—   Medical management of pituitary adenomas became feasible with the availability of bromocriptine, a dopamine agonist that suppresses both PRL and tumor growth in patients with prolactinomas. A number of medications have been used to treat hypercortisolism associated with Cushing's disease including ketoconazole, metyrapone, mitotane, etomidate, cabergoline, pasireotide, and mifepristone. Somatostatin analogs are useful in the therapy of acromegaly and some TSH-secreting adenomas. Specifics of the use of these and other medications are discussed later.

Posttreatment Follow-Up

Patients undergoing transsphenoidal microsurgery should be reevaluated 4 to 8 weeks postoperatively to document that complete removal of the adenoma and correction of endocrine hypersecretion has been achieved. Prolactinomas are assessed by basal PRL measurements, GH-secreting tumors by glucose suppression testing and IGF-1 levels, and ACTH-secreting adenomas by

measurement of late-night salivary cortisol, urine-free cortisol, and the response to low-dose dexamethasone suppression (see later). Other anterior pituitary hormones—TSH and LH/FSH—should also be assessed as described earlier in the section on endocrine evaluation. In patients with successful responses, yearly evaluation should be performed to watch for late recurrence; late hypopituitarism does not occur after microsurgery. MRI is not necessary in patients with normal postoperative pituitary function but should be utilized in patients with persistent or recurrent disease.

Follow-up of patients treated by pituitary irradiation is also essential, because the response to therapy may be delayed and the incidence of hypopituitarism increases with time. Yearly endocrinologic assessment of both the hypersecreted hormone and the other pituitary hormones is recommended.

1. PROLACTINOMAS

PRL hypersecretion is the most common endocrine abnormality due to hypothalamic-pituitary disorders, and PRL is the hormone most commonly secreted in excess by pituitary adenomas.

The understanding is that PRL hypersecretion causes not only galactorrhea but also gonadal dysfunction, and the use of PRL measurements in screening such patients has permitted recognition of these PRL-secreting tumors before the development of sellar enlargement, hypopituitarism, or visual impairment. Thus, plasma PRL should be measured in patients with galactorrhea, suspected hypothalamic-pituitary dysfunction, or sellar enlargement and in those with unexplained gonadal dysfunction, including amenorrhea, infertility, decreased libido, or impotence (Table 4–12).

Pathology

PRL-secreting pituitary adenomas arise most commonly from the lateral wings of the anterior pituitary, but with progression they fill the sella turcica and compress the normal anterior and posterior lobes. Tumor size varies greatly from microadenomas to large invasive tumors with extrasellar extension. Most patients have microadenomas (ie, tumors <1 cm in diameter at diagnosis).

Prolactinomas usually appear chromophobic on routine histologic study, reflecting the inadequacy of the techniques used. The cells are small and uniform, with round or oval nuclei and scanty cytoplasm, and secretory granules are usually not visible with routine stains. The stroma contains a diffuse capillary network.

Electron microscopic examination shows that prolactinoma cells characteristically contain secretory granules that usually

TABLE 4–12 Indications for prolactin measurement.

Galactorrhea
Enlarged sella turcica
Suspected pituitary tumor
Hypogonadotropic hypogonadism
Unexplained amenorrhea
Unexplained male hypogonadism or infertility

range from 100 to 500 nm in diameter and are spherical. Larger granules (400-500 nm), which are irregular or crescent-shaped, are less commonly seen. The cells show evidence of secretory activity, with a large Golgi area, nucleolar enlargement, and a prominent endoplasmic reticulum. Immunocytochemical studies of these tumors have confirmed that the secretory granules indeed contain PRL.

Clinical Features

The clinical manifestations of PRL excess are the same regardless of the cause (see later). The classic features are galactorrhea and amenorrhea in women and decreased libido or impotence in men. Although the sex distribution of prolactinomas is approximately equal, microadenomas are much more common in women, presumably because of earlier recognition of the endocrine consequences of PRL excess.

A. Galactorrhea Galactorrhea occurs in the majority of women with prolactinomas and is much less common in men. It is usually not spontaneous, or may be present only transiently or intermittently. The absence of galactorrhea despite markedly elevated PRL levels is probably due to concomitant deficiency of the gonadal hormones required to initiate lactation (see Chapter 16).

B. Gonadal dysfunction

1. **In women**—Amenorrhea, oligomenorrhea with anovulation, or infertility is present in approximately 90% of women with prolactinomas. These menstrual disorders usually present concurrently with galactorrhea, if it is present, but may either precede or follow it. The amenorrhea is usually secondary and may follow pregnancy or oral contraceptive use. Primary amenorrhea occurs in the minority of patients who have onset of hyperprolactinemia during adolescence. The necessity of measuring PRL in patients with unexplained primary or secondary amenorrhea is emphasized by several studies showing that hyperprolactinemia occurs in as many as 20% of patients with neither galactorrhea nor other manifestations of pituitary dysfunction. A number of these patients have been shown to have prolactinomas.

Gonadal dysfunction in these women is due to interference with the hypothalamic-pituitary-gonadal axis by the hyperprolactinemia and, except in patients with large or invasive adenomas, is not due to destruction of the gonadotropin-secreting cells. This has been documented by the return of menstrual function following reduction of PRL levels to normal by drug treatment or surgical removal of the tumor. Although basal gonadotropin levels are frequently within the normal range despite reduction of sex steroid levels in hyperprolactinemic patients, PRL inhibits both the normal pulsatile secretion of LH and FSH and the midcycle LH surge, resulting in anovulation. The positive feedback effect of estrogen on gonadotropin secretion is also inhibited; in fact, patients with hyperprolactinemia are usually estrogen-deficient.

Estrogen deficiency in women with prolactinomas may be accompanied by decreased vaginal lubrication, other symptoms of estrogen deficiency, and low bone mass as assessed by bone densitometry. Other symptoms may include weight gain, fluid retention, and irritability. Hirsutism may also occur,

accompanied by elevated plasma levels of DHEA sulfate. Patients with hyperprolactinemia may also suffer from anxiety and depression. In small clinical trials, treatment with dopamine agonists has been shown to improve psychologic well-being in such patients.

2. **In men**—In men, PRL excess may also occasionally cause galactorrhea; however, the usual manifestations are those of hypogonadism. The initial symptom is decreased libido, which may be dismissed by both the patient and physician as due to psychosocial factors; thus, the recognition of prolactinomas in men is frequently delayed, and marked hyperprolactinemia (PRL >200 ng/mL [9.1 nmol/L]) and sellar enlargement are usual. Unfortunately, prolactinomas in men are often not diagnosed until late manifestations such as headache, visual impairment, or hypopituitarism appear; virtually all such patients have a history of sexual or gonadal dysfunction. Serum testosterone levels are low, and in the presence of normal or subnormal gonadotropin levels, PRL excess should be suspected as should other causes of hypothalamic-pituitary-gonadal dysfunction (see section on Hypopituitarism). Impotence also occurs in hyperprolactinemic males. Its cause is unclear, because testosterone replacement may not reverse it if hyperprolactinemia is not corrected. Male infertility accompanied by reduction in sperm count is a less common initial complaint.

C. Tumor progression   In general, the growth of prolactinomas is slow; several studies have shown that most microadenomas do not change significantly in size, and macroadenomas tend to grow very slowly.

Differential Diagnosis

The many conditions associated with hyperprolactinemia are listed in Table 4–8. Pregnancy, hypothalamic-pituitary disorders, primary hypothyroidism, and drug ingestion are the most common causes.

Hypothalamic lesions frequently cause PRL hypersecretion by decreasing the secretion of dopamine that tonically inhibits PRL release; the lesions may be accompanied by panhypopituitarism. Similarly, traumatic or surgical section of the pituitary stalk leads to hyperprolactinemia and hypopituitarism. Nonfunctional pituitary macroadenomas frequently cause mild hyperprolactinemia by compression of the pituitary stalk or hypothalamus.

Pregnancy leads to a physiologic increase in PRL secretion; the levels increase as pregnancy continues and may reach 200 ng/mL (9.1 nmol/L) during the third trimester. Following delivery, basal PRL levels gradually fall to normal over several weeks but increase in response to breast feeding. Hyperprolactinemia persisting for 6 to 12 months or longer following delivery is an indication for evaluation. PRL levels are also high in normal neonates.

Several systemic disorders lead to hyperprolactinemia. Primary hypothyroidism is a common cause, and measurement of thyroid function, and especially TSH, should be part of the evaluation. In primary hypothyroidism, there is hyperplasia of both thyrotrophs and lactotrophs, presumably due to TRH hypersecretion. This may result in significant pituitary gland enlargement, which may be mistaken for a PRL-secreting pituitary tumor. The PRL response to TRH is usually exaggerated in these patients. PRL

may also be increased in liver disease, particularly in patients with severe cirrhosis, and in patients with chronic renal failure.

PRL excess and galactorrhea may also be caused by breast disease, nipple stimulation, disease or injury to the chest wall, and spinal cord lesions. These disorders increase PRL secretion by stimulation of afferent neural pathways.

Artifactual elevations in PRL levels may be observed in the presence of anti-PRL antibodies or of macroprolactinemia. In the latter, a high-molecular-weight complex of PRL molecules maintains immunologic activity, but minimal or no bioactivity. Macroprolactinemia can be assessed with polyethylene glycol precipitation of serum samples.

The most common cause of hyperprolactinemia is drug ingestion, and a careful history of drug intake must be obtained. Elevated PRL levels, galactorrhea, and amenorrhea may occur following estrogen therapy or oral contraceptive use, but their persistence should suggest prolactinoma. Many other drugs also cause increased PRL secretion and elevated plasma levels (see Table 4–8). PRL levels are usually less than 200 ng/mL (9 nmol/L), and the evaluation should focus on discontinuation of the drug or medication and reevaluation of the patient after several weeks. In patients in whom drug withdrawal is not feasible, neuroradiologic studies, if normal, usually exclude prolactinoma.

Diagnosis

A. General evaluation   The evaluation of patients with galactorrhea or unexplained gonadal dysfunction with normal or low plasma gonadotropin levels should first include a history regarding menstrual status, pregnancy, fertility, sexual function, and symptoms of hypothyroidism or hypopituitarism. Current or previous use of medication, drugs, or estrogen therapy should be documented. Basal PRL levels, gonadotropins, thyroid function tests, and TSH levels should be established, as well as serum testosterone in men. Liver and kidney function should be assessed. A pregnancy test should be performed in women with amenorrhea.

Patients with galactorrhea but normal menses may not have hyperprolactinemia and usually do not have prolactinomas. If the PRL level is normal, they may be reassured and followed with sequential PRL measurements. Those with elevated levels require further evaluation as described later.

B. Specific diagnosis   When other causes of hyperprolactinemia have been excluded, the most likely cause of persistent hyperprolactinemia is a prolactinoma, especially if there is associated hypogonadism. Because currently available suppression and stimulation tests do not distinguish PRL-secreting tumors from other causes of hyperprolactinemia, the diagnosis must be established by the assessment of both basal PRL levels and neuroradiologic studies. Patients with large tumors and marked hyperprolactinemia usually present little difficulty. With very rare exceptions, basal PRL levels greater than 200 to 300 ng/mL (9.1-13.7 nmol/L) are virtually diagnostic of prolactinoma. In addition, because there is a general correlation between the PRL elevation and the size of the pituitary adenoma, these patients

usually have sellar enlargement and obvious macroadenomas. Similarly, if the basal PRL level is between 100 and 200 ng/mL (4.5 and 9.1 nmol/L), the cause is usually prolactinoma. These patients may have either micro- or macroadenomas; however, with basal levels of PRL greater than 100 ng/mL (4.5 nmol/L), the PRL-secreting tumor is usually radiologically evident, and again the diagnosis is generally straightforward. Patients with mild to moderate hyperprolactinemia (20-100 ng/mL [0.9-4.5 nmol/L]) present the greatest difficulty in diagnosis, because both PRL-secreting microadenomas and the many other conditions causing hyperprolactinemia (see Table 4–8) cause PRL hypersecretion of this degree. In such patients, MRI frequently demonstrates a definite pituitary microadenoma. Scans showing only minor or equivocal abnormalities should be interpreted with caution, because of the high incidence of false-positive scans in the normal population (see Neuroradiologic Evaluation, earlier). Because the diagnosis cannot be either established or excluded in patients with normal or equivocal neuroradiologic studies, they require further evaluation or serial assessment (see later). Dilutions of prolactin samples can be performed in patients with modest prolactin elevation or macroadenomas to rule out interference from the high-dose *hook effect*; large quantities of antigen can impair antigen-antibody binding, resulting in erroneously low prolactin measurements in some immunoassays.

Treatment

Satisfactory control of PRL hypersecretion, cessation of galactorrhea, and return of normal gonadal function can be achieved in most patients with PRL-secreting microadenomas. In patients with hyperprolactinemia, ovulation should not be induced without careful assessment of pituitary anatomy, because pregnancy may cause further expansion of these tumors as discussed later.

Although most microadenomas do not progress, treatment of these patients is recommended to restore normal estrogen levels and fertility and to prevent early osteoporosis secondary to persistent hypogonadism. In addition, medical or surgical therapy is more successful in these patients than in those with larger tumors. All patients with PRL-secreting macroadenomas should be treated, because of the risks of further tumor expansion, hypopituitarism, and visual impairment. Patients with persistent hyperprolactinemia and hypogonadism and normal neuroradiologic studies—that is, those in whom prolactinoma cannot be definitely established—may be managed by observation if hypogonadism is of short duration. However, in patients whose hypogonadism has persisted for more than 6 to 12 months, dopamine agonists should be used to suppress PRL secretion and restore normal gonadal function. In women with macroprolactinomas, replacement estrogen therapy should be initiated only after PRL hypersecretion has been controlled by dopamine agonist therapy since estrogen stimulates lactotroph hyperplasia and may increase tumor size. In this regard, periodic measurement of serum PRL should be performed in women with microadenomas on estrogen therapy who are not also receiving dopamine agonist therapy.

A. Dopamine agonists   Bromocriptine became available in the United States more than 30 years ago and was the first effective medical therapy for pituitary adenomas; however, cabergoline is more potent, much longer acting, and better tolerated. Cabergoline has, therefore, become the dopamine agonist of choice in the therapy of prolactinomas.

1. **Bromocriptine**—Bromocriptine stimulates dopamine receptors and has effects at both the hypothalamic and pituitary levels. It is effective therapy for a PRL-secreting pituitary adenoma and directly inhibits PRL secretion by the tumor. Doses of 2.5 to 5 mg daily are often effective.

2. **Cabergoline**—Cabergoline, a newer nonergot dopamine agonist, is administered once or twice a week and has a better side-effect profile than bromocriptine. It is as effective as bromocriptine in reducing macroadenoma size and is more effective in reducing PRL levels. It has been used successfully in most patients previously intolerant or resistant to bromocriptine. Cabergoline should be started at a dosage of 0.25 to 0.50 mg twice per week. Bedtime administration with a snack seems to reduce side effects. Although several studies demonstrated associations between cabergoline and cardiac valve disease in patients treated for Parkinson disease, clinically relevant valve disease in patients treated for prolactinoma appears to be rare, likely because doses used to manage symptoms of Parkinsonism are often 20 to 30 times higher and administered daily rather than twice weekly. The risk also appears to be related to the affinity of different dopamine agonists for valvular serotonin (5-HT2B) receptors. Until larger, prospective safety studies are available, some authorities recommend echocardiographic evaluation in patients who are expected to need long-term treatment, especially at high doses.

    a. **Microadenomas**—Cabergoline is successful in about 90% of patients, and very few are intolerant or resistant. Correction of hyperprolactinemia allows recovery of normal gonadal function; ovulation and fertility are restored, so that barrier and non-hormonal forms of contraception should be advised if pregnancy is not desired. Both bromocriptine and cabergoline are now considered to be safe for the restoration of the hypothalamic-pituitary-gonadal axis and ovulation induction. In patients with microadenomas, the risk of major expansion of adenoma during the pregnancy is less than 2%; however, both the patient and the physician must be aware of this potential complication. Current data do not indicate an increased risk of multiple pregnancy, abortion, or fetal malformations in pregnancies occurring in women taking dopamine agonists; however, patients should be instructed to discontinue these drugs at the first missed menstrual period and obtain a pregnancy test. Although no late toxicity has yet been reported other than the side effects noted earlier, questions about possible long-term risk are currently unanswered. Maternal hyperprolactinemia should not be harmful to the developing fetus; prolactin increases normally during pregnancy and does not appear to cross the placenta.

    b. **Macroadenomas**—Dopamine agonists are effective in controlling hyperprolactinemia in patients with PRL-secreting macroadenomas even when basal PRL levels are markedly elevated. Dopamine agonists may be used either as initial therapy or to control residual hyperprolactinemia in patients unsuccessfully treated with surgery or radiotherapy. Dopamine agonists should not be used to induce ovulation and

pregnancy in women with untreated macroadenomas, because the risk of tumor expansion and visual deficits in the later part of pregnancy is approximately 15% to 25%. These patients should first have tumor volume decreased with medical therapy or be treated with surgery prior to induction of ovulation.

Dopamine agonists normalize PRL secretion in about 60% to 70% of patients with macroadenomas and also reduce tumor size in about the same percentage of patients. Reduction of tumor size may occur within days to weeks following institution of therapy. The drugs have been used to restore vision in patients with major suprasellar extension and chiasmal compression.

c. **Long-term remission**—Current studies suggest that 30% to 40% of patients with micro- and macroadenomas will remain in long-term remission after withdrawal of cabergoline therapy of 2 to 3 years duration provided that they have normalization of PRL levels and tumor shrinkage. Larger macroadenomas (>2.0 cm) are likely to recur, and long-term dopamine agonist therapy should be continued in these patients.

B. Surgical treatment   Transsphenoidal microsurgery is the surgical procedure of choice in patients with prolactinomas.

1. **Microadenomas**—In patients with microadenomas, remission, as measured by restitution of normal PRL levels, normal menses, and cessation of galactorrhea, is achieved in 85% to 90% of cases. Success is most likely in patients with basal PRL levels under 200 ng/mL (9.1 nmol/L) and duration of amenorrhea of less than 5 years. In these patients, the incidence of surgical complications is less than 2%, and hypopituitarism is a rare complication. Thus, in this group of patients with PRL-secreting microadenomas, PRL hypersecretion can be corrected, gonadal function restored, and secretion of TSH and ACTH preserved. Recurrence rates vary considerably in reported series. In our experience, approximately 85% of patients have had long-term remissions, and 15% have had recurrent hyperprolactinemia.

2. **Macroadenomas**—Transsphenoidal microsurgery is considerably less successful in restoring normal PRL secretion in patients with macroadenomas; many clinicians would treat these patients with dopamine agonists alone. The surgical outcome is directly related to tumor size and the basal PRL level. Thus, in patients with tumors 1 to 2 cm in diameter without extrasellar extension and with basal PRL levels less than 200 ng/mL (9.1 nmol/L), transsphenoidal surgery is successful in about 80% of cases. In patients with higher basal PRL levels and larger or invasive tumors, the success rate—defined as complete tumor resection and restoration of normal basal PRL secretion—is 25% to 50%. Although progressive visual loss or pituitary apoplexy is a clear indication for surgery, the great majority of these patients should be treated with dopamine agonists.

C. Radiotherapy   Conventional radiation therapy is reserved for patients with PRL-secreting macroadenomas who have persistent hyperprolactinemia and who have not responded to attempts to control their pituitary adenomas with surgery or dopamine agonists. In this group of patients, radiotherapy with 4000 to 5000 cGy prevents further tumor expansion, although

PRL levels usually do not fall into the normal range. Impairment of anterior pituitary function occurs in approximately 50% to 60% of patients. Experience with gamma knife radiosurgery in prolactinomas is limited and rates of remission and reduction in tumor volume have been reported with varying degrees of success.

Selection of Therapy for Prolactinomas

The selection of therapy for prolactinomas depends on the wishes of the patient, the patient's plans for pregnancy and tolerance of medical therapy, and the availability of a skilled neurosurgeon.

A. Microadenomas   Most men and premenopausal women should be treated to prevent the occasional tumor progression, loss of bone mass, and the other effects of prolonged hypogonadism. Medical therapy with cabergoline effectively restores normal gonadal function and fertility, and pregnancy carries only a small risk of tumor expansion. Those patients who respond should be treated for 2 to 3 years, and then the drug should be withdrawn to determine if long-term remission will occur. Patients who have recurrence of hyperprolactinemia after cabergoline withdrawal may resume the drug or choose to have surgical excision. In asymptomatic postmenopausal women who decide against using medical therapy, intermittent monitoring of prolactin as a marker of tumor enlargement should be performed. Transsphenoidal adenectomy, either initially or after a trial of dopamine agonist therapy, carries little risk when performed by an experienced neurosurgeon and offers a high probability of long-term remission.

B. Macroadenomas   Primary surgical therapy in these patients usually does not result in long-term remission, so medical therapy is the primary therapy of choice, particularly when the patient's PRL levels are greater than 200 ng/mL (9.1 nmol/L) and the tumor is larger than 2 cm. Although transsphenoidal microsurgery rapidly decreases tumor size and decompresses the pituitary stalk, the optic chiasm, and the cavernous sinuses, there is usually residual tumor and hyperprolactinemia. Thus, these patients require additional therapy with dopamine agonists. Although tumor growth and PRL secretion can be controlled by medical therapy in most patients, therapeutic failure can result from drug intolerance, poor compliance, or resistance. Radiation therapy is reserved for postsurgical patients with residual adenomas who are not controlled with dopamine agonists.

2. ACROMEGALY AND GIGANTISM

GH-secreting pituitary adenomas are second in frequency to prolactinomas for functioning pituitary tumors and cause the classic clinical syndromes of acromegaly and gigantism.

The characteristic clinical manifestations are the consequence of chronic GH hypersecretion, which in turn leads to excessive generation of IGF-1, the mediator of most of the effects of GH (see Chapter 6). Although overgrowth of bone is the classic

feature, GH excess causes a generalized systemic disorder with deleterious effects and an increased mortality rate, although deaths are rarely due to the space-occupying or destructive effects of pituitary adenoma per se.

Acromegaly and gigantism are virtually always secondary to a pituitary adenoma. Ectopic GHRH secretion has been identified as another cause of GH hypersecretion and acromegaly in a few patients with carcinoid or islet cell tumors. Reports of intrapituitary GHRH-secreting gangliocytomas in direct contiguity with GH-secreting somatotroph adenomas and a report of a GHRH-secreting hypothalamic hamartoma in a patient with acromegaly provide a link between ectopic and eutopic GHRH production. Ectopic secretion of GH per se is very rare but has been documented in a few lung tumors.

In adults, GH excess leads to acromegaly, the syndrome characterized by local overgrowth of bone, particularly of the skull and mandible. Linear growth does not occur, because of prior fusion of the epiphyses of long bones. In childhood and adolescence, the onset of chronic GH excess leads to gigantism. Most of these patients have associated hypogonadism, which delays epiphysial closure and the combination of IGF-1 excess and hypogonadism leads to a striking acceleration of linear growth. Most patients with gigantism also have features of acromegaly if GH hypersecretion persists through adolescence and into adulthood.

Pathology

Pituitary adenomas causing acromegaly are usually more than 1 cm in diameter when the diagnosis is established. These tumors arise from the lateral wings of the anterior pituitary; less than 10% are diagnosed as microadenomas.

GH-secreting adenomas are of two histologic types: densely and sparsely granulated. However, there appears to be no difference in the degree of GH secretion or clinical manifestations in these patients. About 15% of GH-secreting tumors also contain lactotrophs, and these tumors thus hypersecrete both GH and PRL.

Etiology and Pathogenesis

In most cases, excessive pituitary GH secretion is a primary pituitary disorder. A somatic mutation in the G_s protein leading to excessive cAMP production has been identified in 40% of GH-secreting adenomas. Familial isolated pituitary adenomas (FIPA) is characterized by genetic defects in the aryl hydrocarbon receptor interacting protein (AIP) gene, which probably acts as a tumor suppressor. A recently described syndrome of pituitary gigantism termed X-linked acrogigantism (X-LAG) appears to be due to genomic duplication of Xq26.3 (which includes the *GPR101* gene) (see Table 4–10). Pituitary adenomas are present in virtually all patients and are usually greater than 1 cm in diameter; hyperplasia alone is rare, and nonadenomatous anterior pituitary tissue does not exhibit somatotroph hyperplasia when examined histologically. In addition, there is a return of normal GH levels and dynamic control of GH secretion following selective removal of the pituitary adenoma.

Pathophysiology

In acromegaly, GH secretion is increased and its dynamic control is abnormal. Secretion remains episodic; however, the number, duration, and amplitude of secretory episodes are increased, and they occur randomly throughout the 24-hour period. The characteristic nocturnal surge is absent, and there are abnormal responses to suppression and stimulation. Thus, glucose suppressibility is lost (see Diagnosis, later), and GH stimulation by hypoglycemia is usually absent. TRH and GnRH may cause GH release, whereas these substances do not normally stimulate GH secretion. Dopamine and dopamine agonists such as bromocriptine and apomorphine, which normally stimulate GH secretion, paradoxically cause GH suppression in about 70% to 80% of patients with acromegaly.

Most of the deleterious effects of chronic GH hypersecretion are caused by its stimulation of excessive amounts of IGF-1 (see Chapter 6), and plasma levels of this protein are increased in acromegaly. The growth-promoting effects of IGF-1 (DNA, RNA, and protein synthesis) lead to the characteristic proliferation of bone, cartilage, and soft tissues and increase in size of other organs to produce the classic clinical manifestations of acromegaly. The insulin resistance and carbohydrate intolerance seen in acromegaly appear to be direct effects of GH and not due to IGF-1 excess.

Clinical Features

The sex incidence of acromegaly is approximately equal; the mean age at diagnosis is approximately 40 years; and the duration of symptoms is usually 5 to 10 years before the diagnosis is established.

Acromegaly is a chronic disabling and disfiguring disorder with increased late morbidity and mortality if untreated. Although spontaneous remissions have been described, the course is slowly progressive in the great majority of cases.

A. Symptoms and signs   Early manifestations (Table 4–13) include soft tissue proliferation, with enlargement of the hands and feet and coarsening of the facial features. This is usually accompanied by increased sweating, heat intolerance, oiliness of the skin, fatigue, and weight gain.

At diagnosis, most patients have classic manifestations, and acral and soft tissue changes are always present. Bone and cartilage changes affect chiefly the face and skull. These changes include thickening of the calvarium; increased size of the frontal sinuses, which leads to prominence of the supraorbital ridges; enlargement of the nose; and downward and forward growth of the mandible, which leads to prognathism and widely spaced teeth. Soft tissue growth also contributes to the facial appearance, with coarsening of the features and facial and infraorbital puffiness. The hands and feet are predominantly affected by soft tissue growth; they are large, thickened, and bulky, with blunt, spade-like fingers (Figure 4–19) and toes. A bulky, sweaty handshake frequently suggests the diagnosis, and there are increases in ring, glove, and shoe sizes. There is generalized thickening of the skin, with increased oiliness and sweating. Acne, sebaceous cysts, and fibromata mollusca (skin tags

TABLE 4–13 Clinical manifestations of acromegaly in 100 patients.

Manifestations of GH excess	
Acral enlargement	100[a]
Soft tissue overgrowth	100
Hyperhidrosis	88
Lethargy or fatigue	87
Weight gain	73
Paresthesias	70
Joint pain	69
Photophobia	46
Papillomas	45
Hypertrichosis	33
Goiter	32

and papillomas) are common, as is acanthosis nigricans of the axillae and neck and hypertrichosis in women.

These bony and soft tissue changes are accompanied by systemic manifestations, which include hyperhidrosis, heat intolerance, lethargy, fatigue, and increased sleep requirement. Sleep apnea, both obstructive and central, is very common in patients with acromegaly. This has particular importance for the anesthesiologist who must take special precautions to protect the airway during surgery. Moderate weight gain usually occurs. Paresthesias, usually due to carpal tunnel compression, occur in 70%; sensorimotor neuropathies occur uncommonly. Bone and cartilage overgrowth leads to arthralgias and in longstanding cases to degenerative arthritis of the spine, hips, and knees. Photophobia of unknown cause occurs in about half of cases and is most troublesome in bright sunlight and during night driving.

GH excess leads to generalized visceromegaly, clinically evident as thyromegaly and enlargement of the salivary glands. Enlargement of other organs is usually not clinically detectable.

Hypertension occurs in about 25% of patients and cardiomegaly in about 15%. Cardiac enlargement may be secondary to hypertension, atherosclerotic disease, or, rarely, to acromegalic cardiomyopathy. Renal calculi occur in 11% secondary to the hypercalciuria induced by GH excess.

Other endocrine and metabolic abnormalities are common and may be due either to GH excess or to mechanical effects of the pituitary adenoma. Glucose intolerance and hyperinsulinism occur in 50% and 70% of patients, respectively, owing to GH-induced insulin resistance. Overt clinical diabetes occurs in a minority, and diabetic ketoacidosis is rare. Hypogonadism occurs in 60% of female and 46% of male patients and is of multifactorial origin; tumor growth and compression may impair pituitary gonadotropin secretion, and associated hyperprolactinemia (see later) or the PRL-like effect of excessive GH secretion may impair gonadotropin and gonadal function. In men, low total plasma testosterone levels may be due to GH suppression of sex hormone–binding globulin (SHBG) levels; in these cases, plasma-free testosterone levels may be normal, with normal gonadal function. With earlier diagnosis, hypothyroidism and hypoadrenalism due to destruction of the normal anterior pituitary are unusual and are

FIGURE 4–19 Markedly increased soft tissue bulk and blunt fingers in a middle-aged man with acromegaly.

present in only 13% and 4% of patients, respectively. Galactorrhea occurs in about 15% and is usually caused by hyperprolactinemia from a pituitary adenoma with a mixed cell population of somatotrophs and lactotrophs. Gynecomastia of unknown cause occurs in about 10% of men. Although acromegaly may be a component of MEN type 1 syndrome, it is distinctly unusual, and concomitant parathyroid hyperfunction or pancreatic islet cell tumors are rare.

When GH hypersecretion is present for many years, late complications occur, including progressive cosmetic deformity and disabling degenerative arthritis. In addition, the mortality rate is increased; after age 45, the death rate in acromegaly from cardiovascular and cerebrovascular atherosclerosis, respiratory diseases, and colon cancer is two to four times that of the normal population. Death rates tend to be higher in patients with hypertension, cardiovascular disease, or clinical diabetes mellitus.

Space-occupying manifestations of the pituitary adenoma are also common in acromegaly (eg, 65% of patients have headache). Although visual impairment was usually present in older series, it now occurs in only 15% to 20%, because most patients are now diagnosed because of the manifestations of GH excess.

B. Laboratory findings   In addition to elevations in IGF-1 and GH, postprandial plasma glucose may be elevated, and serum insulin is increased in 70% of cases. Elevated serum phosphate (due to increased renal tubular resorption) and hypercalciuria appear to be due to direct effects of GH or IGF-1.

C. Imaging studies   Plain films (Figure 4–20) show sellar enlargement in 90% of cases. Thickening of the calvarium, enlargement of the frontal and maxillary sinuses, and enlargement of the jaw can also be seen. Radiographs of the hand show increased soft tissue bulk, "arrowhead" tufting of the distal phalanges, increased width of intra-articular cartilages, and cystic changes of the carpal bones. Radiographs of the feet show similar changes, and there is increased thickness of the heel pad (normal, <22 mm).

Diagnosis

Acromegaly is usually clinically obvious and can be readily confirmed by assessment of GH secretion; basal fasting GH levels (normal, 1-5 ng/mL [46-232 pmol/L]) are greater than 10 ng/mL (465 pmol/L) in more than 90% of patients and range from 5 ng/mL (232 pmol/L) to greater than 500 ng/mL (23,000 pmol/L), with a mean of approximately 50 ng/mL (2300 pmol/L). However, single measurements are not entirely reliable, because GH secretion is episodic in acromegaly and because other conditions may increase GH secretion (see discussed later).

A. Glucose suppression   Suppression with oral glucose is the simplest and most specific dynamic test for acromegaly. In healthy subjects, oral administration of 100 g of glucose causes a reduction of the GH level to less than 1 ng/mL (47 pmol/L) at 60 minutes. In acromegaly, GH levels may decrease, increase, or show no change; however, they do not decrease to less than
FIGURE 4–20 Radiologic signs in acromegaly. **A**: Skull with enlarged sella turcica and frontal sinuses, thickening of the calvarium, and enlargement of the mandible. **B**: Hand with enlarged sesamoid bone and increased soft tissue shadows. **C**: Thickened heel pad. 1 ng/mL (47 pmol/L), and this lack of response establishes the diagnosis. Supersensitive GH assays have been developed and are becoming commercially available. With these assays, normal individuals may suppress GH levels to less than 0.1 ng/mL. Thus, the criteria expressed earlier may need to be adjusted in the near future (to <0.04 ng/mL). Since many assays lack sufficient accuracy; however, a cutoff of less than 0.1 ng/mL is still recommended.

B. IGF-1 measurement   Measurement of IGF-1 (see Chapter 6) is a useful means of establishing the diagnosis of GH hypersecretion. IGF-1 results must be interpreted according to age- and sex-adjusted normative data. IGF-1 levels directly reflect GH activity. IGF-1 has a long half-life, so that IGF-1 levels fluctuate much less than GH levels. IGF-1 levels are

elevated in virtually all patients with acromegaly (normal ranges vary widely in different laboratories, and some commercial assays are not reliable).

C. Tumor localization Radiographic localization of the pituitary adenoma causing acromegaly is usually straightforward (see Neuroradiologic Evaluation, earlier). In virtually all patients, tumor location and size can be shown by MRI; 90% have tumors greater than 1 cm in diameter that are readily visualized. In the rare patient with normal neuroradiologic studies, an extrapituitary ectopic source of GH or GHRH should be considered. If scans suggest diffuse pituitary enlargement or hyperplasia, ectopic GHRH should also be suspected.

Differential Diagnosis

A. Other causes of GH or IGF-1 hypersecretion The presence of clinical features of GH excess, elevated GH and IGF-1 secretion, and abnormal GH dynamics, together with the demonstration of a pituitary tumor by neuroradiologic studies, are diagnostic of acromegaly. However, other conditions associated with GH hypersecretion must be considered in the differential diagnosis. These include anxiety, exercise, acute illness, chronic renal failure, cirrhosis, starvation, protein-calorie malnutrition, anorexia nervosa, and type 1 (insulin-dependent) diabetes mellitus. Estrogen therapy may increase GH responsiveness to various stimuli. These conditions may be associated with abnormal GH suppressibility by glucose and by abnormal GH responsiveness to TRH; however, patients with these conditions do not have clinical manifestations of GH excess and are thus readily differentiated from patients with acromegaly. In addition, the conditions listed earlier do not lead to elevation of IGF-1 concentrations. Use of testosterone or the contraceptive depot medroxyprogesterone acetate has been associated with modest elevations in IGF-1.

B. Ectopic GH or GHRH secretion These rare patients with acromegaly due to ectopic secretion of GH or GHRH have typical clinical manifestations of acromegaly. This may occur in lung carcinoma, carcinoid tumors, and pancreatic islet cell tumors. These syndromes should be suspected in patients with a known extrapituitary tumor who have GH excess or in those with clinical and biochemical features of acromegaly who have radiologic procedures that show normal pituitary glands or that suggest diffuse pituitary enlargement or hyperplasia.

Treatment

All patients with acromegaly should undergo therapy to halt progression of the disorder and to prevent late complications and excess mortality. The objectives of therapy are removal or destruction of the pituitary tumor, reversal of GH hypersecretion, and maintenance of normal anterior and posterior pituitary function. These objectives are currently attainable in most patients, especially those with smaller tumors and only moderate GH hypersecretion. In patients with large tumors who have marked GH hypersecretion, several therapies are usually required to achieve normal GH secretion.

The criteria for an adequate response to therapy continue to evolve. Some reports have described increased late mortality in patients with GH levels by radioimmunoassay greater than 2.5 ng/mL (116 pmol/L) after therapy. Therefore, current guidelines for remission are a fasting GH of 1 ng/mL (47 pmol/L) or less and a glucose-suppressed GH of 1 ng/mL (47 pmol/L) or less accompanied by a normal level of IGF-1.

The initial therapy of choice is transsphenoidal microsurgery because of its high success rate, rapid reduction of GH levels, the low incidence of postoperative hypopituitarism, and the low surgical morbidity rate. Patients with persisting GH hypersecretion after surgery should be treated medically with somatostatin analogs, dopamine agonists, or a GH receptor antagonist. Radiation therapy should be reserved for those patients with inadequate responses to surgery and medical therapy.

A. Surgical treatment Transsphenoidal selective adenoma removal is the procedure of choice; craniotomy is necessary in the rare patient in whom major suprasellar extension precludes the transsphenoidal approach. Successful reduction of GH levels is achieved in approximately 60% to 80% of patients. In those with small or moderate-sized tumors (<2 cm), success is achieved in more than 80%, whereas in those with larger tumors and basal GH levels greater than 50 ng/mL (2325 pmol/L)—and particularly in those with major extrasellar extension of the adenoma—successful responses occur in only 30% to 60%. Recurrence rates in those with a successful initial response are low (about 5% of patients at our institution). Surgical complications (discussed earlier) occur in less than 2%.

B. Medical treatment Octreotide acetate, a somatostatin analog, was the first effective medical therapy for patients with acromegaly. However, the drug required high doses (100-500 µg) given subcutaneously three times daily. Its use in acromegaly has been superseded by sustained-release somatostatin analogs with activities lasting up to 1 month. Preparations include octreotide LAR, lanreotide acetate, and pasireotide diaspartate given by injection every 4 weeks. Octreotide LAR normalizes GH and IGF-1 levels in 75% of patients when used at doses of 20 to 40 mg/mo; however, tumor reduction occurs in a much smaller percentage. Pasireotide binds with high affinity to 4 of the 5 somatostatin receptor subtypes and may be more effective than octreotide at normalizing GH and IGF-1 levels. The long-acting agents have become the therapy of choice for patients with residual GH hypersecretion following surgery. Side effects of this class of agents consist mainly of gastrointestinal symptoms and the development of gallstones. Impaired glucose tolerance has been reported, especially with pasireotide.

The dopamine agonist cabergoline normalizes IGF-1 levels in about 30% of acromegalic patients when used at doses of 1 to 2 mg/wk. However, it has not been commonly used as sole therapy. When cabergoline is added to somatostatin analog therapy, the number of patients with normalization of GH and IGF-1 levels is increased.

Pegvisomant is a GH receptor antagonist that has been shown to be an effective therapy for the treatment of acromegaly. In doses of 10 to 20 mg/d given by subcutaneous injection, it reduces IGF-1 levels to normal in more than 90% of patients. Although there are concerns regarding the continued excess GH secretion and possible tumor progression, serious problems have not arisen to date. Although pegvisomant has very good efficacy, its use may be limited by its high cost and the need for daily injections. Accordingly, it is currently used mainly in those patients who have failed therapy with surgery and somatostatin analogs.

C. Radiotherapy   Conventional supervoltage irradiation in doses of 4500 to 5000 cGy, although ultimately successful in 60% to 80% of patients, should not be used, because GH levels may not return to normal until 10 to 15 years after therapy. In one series, GH levels were under 10 ng/mL (460 pmol/L) in only 38% of patients at 2 years posttreatment; however, at 5 and 10 years, 73% and 81% had achieved such levels. The incidence of hypopituitarism is appreciable, and in this series hypothyroidism occurred in 19%, hypoadrenalism in 38%, and hypogonadism in approximately 50% to 60% of patients as a consequence of radiotherapy. Gamma knife radiosurgery has also been used for tumors confined to the sella. Current series, although limited, suggest remission rates of about 50% to 70% at 2 years following therapy.

Response to Treatment

In patients with successful reduction in GH hypersecretion, there is cessation of bone overgrowth. In addition, these patients experience considerable clinical improvement, including reduction in soft tissue bulk of the extremities, decreased facial puffiness, increased energy, and cessation of hyperhidrosis, heat intolerance, and oily skin. Bony changes typically do not regress. Headache, carpal tunnel syndrome, arthralgias, sleep apnea, and photophobia are also reversible with successful therapy. Glucose intolerance and hyperinsulinemia as well as hypercalciuria are also reversed in most cases. Excess mortality associated with acromegaly can be reversed if GH levels are normalized.

Posttreatment Follow-Up

Posttreatment assessment includes evaluation of GH secretion, anterior pituitary function, and tumor size. Patients undergoing surgery should postoperative assessment of pituitary function. Measurement of IGF-1 and GH should be performed at 12 weeks or later. If GH is >1 ng/mL, measure nadir GH level after a glucose load. Those with persistent GH hypersecretion (>1 ng/mL [47 pmol/L]) should receive further therapy with somatostatin analogs. Patients with postoperative GH levels under 1 ng/mL (47 pmol/L) should have follow-up GH and IGF-1 determinations at 6-month intervals for 2 years and yearly thereafter to rule out recurrences. Recurrent elevations in IGF-1 should prompt a repeat MRI of the sella. Late hypopituitarism after surgery alone does not occur. GH replacement therapy in patients with history of acromegaly and hypopituitarism is controversial and further studies are needed.

3. ACTH-SECRETING PITUITARY ADENOMAS: CUSHING DISEASE

In 1932, Harvey Cushing documented the presence of small basophilic pituitary adenomas in six of eight patients with clinical features of adrenocortical hyperfunction. Years later, ACTH hypersecretion was identified from such tumors and found to be the cause of bilateral adrenal hyperplasia. Pituitary ACTH hypersecretion (Cushing disease) is now recognized as the most common cause of endogenous hypercortisolism (Cushing syndrome) and must be distinguished from the other forms of adrenocorticosteroid excess—ectopic ACTH syndrome and adrenal tumors (see Chapter 9).

Pathology

ACTH-secreting pituitary tumors exist in virtually all patients with Cushing disease. These tumors are usually benign microadenomas under 10 mm in diameter; 50% are 5 mm or less in diameter, and microadenomas as small as 1 mm have been described. These tumors in Cushing disease are either basophilic or chromophobe adenomas and may be found anywhere within the anterior pituitary. Rarely, ACTH-secreting tumors are large, with invasive tendencies, and malignant tumors have rarely been reported.

Histologically, the tumors are composed of compact sheets of uniform, well-granulated cells (granule size, 200-700 nm by electron microscopy) with a sinusoidal arrangement and a high content of ACTH and its related peptides (β-LPH, β-endorphin). A zone of perinuclear hyalinization (Crooke changes) is frequently observed as a result of exposure of the corticotroph cells to prolonged hypercortisolism (see Figure 4–7). A specific ultrastructural finding in these adenomas is the deposition of bundles of perinuclear microfilaments that encircle the nucleus; these are the ultrastructural equivalent of Crooke hyaline changes seen on light microscopy. In contrast to the adenoma's cells, ACTH content in the portion of the anterior pituitary not involved with the tumor is decreased.

Diffuse hyperplasia of anterior pituitary corticotrophs or adenomatous hyperplasia, presumed to result from hypersecretion of CRH, occurs rarely.

The adrenal glands in Cushing disease are enlarged, weighing 12 to 24 g (normal, 8-10 g). Microscopic examination shows a thickened cortex due to hyperplasia of both the zona reticularis and zona fasciculata; the zona glomerulosa is normal. In some cases, ACTH-secreting pituitary adenomas cause bilateral nodular hyperplasia; the adrenals show diffuse bilateral cortical hyperplasia and the presence of one or more nodules that vary from microscopic to several centimeters in diameter, with multiple small nodules being the most common.

Pathogenesis

The weight of current evidence is that Cushing disease is a primary pituitary disorder and that hypothalamic abnormalities are secondary to hypercortisolism. The endocrine abnormalities in Cushing disease are as follows: (1) hypersecretion of ACTH, with bilateral adrenocortical hyperplasia and hypercortisolism; (2) absent circadian periodicity of ACTH and cortisol secretion;

(3) absent responsiveness of ACTH and cortisol to stress (hypoglycemia or surgery); (4) abnormal negative feedback of ACTH secretion by glucocorticoids; and (5) subnormal responsiveness of GH, TSH, and gonadotropins to stimulation.

Evidence that Cushing disease is a primary pituitary disorder is based on the high frequency of pituitary adenomas, the response to their removal, and the interpretation of hypothalamic abnormalities as being secondary to hypercortisolism. In addition, molecular studies have found that nearly all corticotroph adenomas are monoclonal. The ubiquitin-specific protease 8 gene (*USP8*) has been found to be mutated in some corticotroph adenomas. The product of this gene has deubiquitinase activity and appears to be involved in the regulation of epidermal growth factor receptor (EGFR) recycling. These findings suggest that ACTH hypersecretion arises from a spontaneously developing pituitary adenoma and that the resulting hypercortisolism suppresses the normal hypothalamic-pituitary axis and CRH release, thereby abolishing the hypothalamic regulation of circadian variability and stress responsiveness.

Analysis of the response to therapy by pituitary microsurgery sheds some light on the pathogenesis of Cushing disease. Selective removal of pituitary microadenomas by transsphenoidal microsurgery corrects ACTH hypersecretion and hypercortisolism in most patients. After selective removal of the pituitary adenoma, the following return to normal: the circadian rhythmicity of ACTH and cortisol, the responsiveness of the hypothalamic-pituitary axis to hypoglycemic stress, and the dexamethasone suppressibility of cortisol secretion.

Clinical Features

Cushing disease presents with the signs and symptoms of hypercortisolism and adrenal androgen excess (see Chapter 9). The onset of these features is usually insidious, developing over months or years. Obesity (with predominantly central fat distribution), hypertension, glucose intolerance, and gonadal dysfunction (amenorrhea or impotence) are common features. Other common manifestations include moon (rounded) facies, plethora, osteopenia, proximal muscle weakness, easy bruisability, psychologic disturbances, violaceous striae, hirsutism, acne, poor wound healing, and superficial fungal infections. Unlike patients with the classic form of ectopic ACTH syndrome, patients with Cushing disease rarely have hypokalemia, weight loss, anemia, or hyperpigmentation. Virilization, observed occasionally in patients with adrenal carcinoma, is unusual in Cushing disease. Clinical symptoms related to the ACTH-secreting primary tumor itself, such as headache or visual impairment, are rare because of the small size of these adenomas.

The usual age range is 20 to 40 years, but Cushing disease has been reported in infants and in patients over 70 years. There is a female:male ratio of approximately 8:1. In contrast, the ectopic ACTH syndrome occurs more commonly in men (male:female ratio of 3:1).

Diagnosis

The initial step in the diagnosis of an ACTH-secreting pituitary adenoma is the documentation of endogenous hypercortisolism, which is confirmed by increased urinary free cortisol secretion, abnormal cortisol suppressibility to low-dose dexamethasone, and/or abnormal late night salivary cortisol measurement. The differentiation of an ACTH-secreting pituitary tumor from other causes of hypercortisolism must be based on biochemical studies, including the measurement of basal plasma ACTH levels and central venous sampling, to detect a central to peripheral gradient of ACTH levels (see Chapter 9). Imaging of the sella with MRI may help to identify a pituitary adenoma in only 50% to 70% of patients with ACTH-dependent hypercortisolism. The diagnosis and differential diagnosis of Cushing syndrome are presented in Chapter 9.

Treatment

Transsphenoidal microsurgery is the procedure of choice in Cushing disease. A variety of other therapies—operative, radiologic, pharmacologic—are discussed later.

A. Surgical treatment Selective transsphenoidal resection of ACTH-secreting pituitary adenomas is the initial treatment of choice. At operation, meticulous exploration of the intrasellar contents by an experienced neurosurgeon is required. The tumor, which is usually found within the anterior lobe tissue, is selectively removed, and normal gland is left intact.

In about 85% of patients with microadenomas, selective microsurgery is successful in correcting hypercortisolism. Surgical damage to anterior pituitary function is rare, but most patients develop transient secondary adrenocortical insufficiency requiring postoperative glucocorticoid support until the hypothalamic-pituitary-adrenal axis recovers, usually in 2 to 18 months. The role of total hypophysectomy is currently unclear; however, hemihypophysectomy based on central venous sampling lateralization is successful in only about 50% to 70% of patients.

By contrast, transsphenoidal surgery is successful in only 25% of the 10% to 15% of patients with Cushing disease with pituitary macroadenomas or in those with extrasellar extension of tumor.

Transient diabetes insipidus occurs in about 10% of patients, but other surgical complications (eg, hemorrhage, cerebrospinal fluid rhinorrhea, infection, visual impairment, permanent diabetes insipidus) are rare. Hypopituitarism occurs only in patients who undergo total hypophysectomy.

Before the introduction of pituitary microsurgery, bilateral total adrenalectomy was the preferred treatment of Cushing disease and may still be employed in patients in whom other therapies are unsuccessful. Total adrenalectomy, which can now be performed laparoscopically, corrects hypercortisolism but produces permanent hypoadrenalism, requiring lifelong glucocorticoid and mineralocorticoid therapy. The ACTH-secreting pituitary adenoma persists and may progress, causing hyperpigmentation and invasive complications (Nelson syndrome; see later). Persistent hypercortisolism may occasionally follow total adrenalectomy as ACTH hypersecretion stimulates adrenal remnants or congenital rests.

B. Radiotherapy Conventional radiotherapy of the pituitary is of benefit in patients who have persistent or recurrent

disease following pituitary microsurgery. In these patients, reported remission rates are 55% to 70% at 1 to 3 years after radiotherapy.

Gamma knife radiosurgery achieves remission rates of 65% to 75%. However, as noted earlier, both forms of radiotherapy cause late loss of pituitary function in more than 50% of patients and visual deficits can occur with damage to the optic chiasm or cranial nerves.

C. Medical treatment Drugs that inhibit adrenal cortisol secretion are useful in Cushing disease, often as adjunctive therapy (see Chapter 9).

Ketoconazole, an imidazole derivative, has been found to inhibit adrenal steroid biosynthesis. It inhibits the cytochrome P450 enzymes P450scc and P450c11. In daily doses of 600 to 1200 mg, ketoconazole has been effective in the management of Cushing syndrome. Hepatotoxicity is common, however, but may be transient. **Metyrapone**, which inhibits P450c11, has also been utilized to reduce cortisol hypersecretion. The use of these drugs is accompanied by increased ACTH levels that may overcome the enzyme inhibition. In addition, they cause gastrointestinal side effects that may limit their effectiveness. More effective control of hypercortisolism with fewer side effects is obtained by combined use of these agents. Adequate data are not available on the long-term use of these drugs as the sole treatment of Cushing disease. Thus, ketoconazole and metyrapone are generally used while awaiting a response to therapy or in the preparation of patients for surgery.

The adrenolytic drug **mitotane** results in adrenal atrophy predominantly of the zonae fasciculata and reticularis. Remission of hypercortisolism is achieved in approximately 80% of patients with Cushing disease, but most relapse after therapy is discontinued. Mitotane therapy is limited by the delayed response, which may take weeks or months, and by the frequent side effects, including severe nausea, vomiting, diarrhea, somnolence, and skin rash.

The anesthesia induction agent **etomidate** inhibits P450c11. It must be given intravenously and is generally reserved for life-threatening cases of hypercortisolism resistant to conventional therapy or when oral medications are contraindicated.

Pituitary-directed therapies include **cabergoline** and **pasireotide diaspartate**. The type 2 dopamine (D2) receptor is present on the majority of corticotroph adenomas. Doses of cabergoline of 1 to 7 mg per week has been shown to be effective at normalizing urinary free cortisol levels in 10% to 30% of patients, can be given orally, and is generally well tolerated. In clinical practice, its role is in a minority of patients with mild hypercortisolism. Pasireotide is a somatostatin (sst) analog that binds with high affinity to sst_1, sst_2, sst_3, and especially sst_5 subtypes of the sst receptor which are present on corticotroph tumors. It was approved for clinical use at doses of 0.6 to 0.9 mg subcutaneously twice daily. In one study, urinary free cortisol normalized in 20% of patients and remained controlled at 12 months. In patients who do not respond after 3 months of therapy despite titration to 0.9 mg twice daily, it should be discontinued or combined with another therapy. Like other sst analogs, adverse effects include gallstones and gastrointestinal

symptoms. Hyperglycemia appears to be more common, however, occurring in a majority of patients. Over half required glucose-lowering therapy in one study. **Mifepristone** is a glucocorticoid-receptor antagonist approved for treatment of hyperglycemia in patients with Cushing syndrome in the United States. It is best known for its anti-progestational properties (RU-486) and has been used for the treatment of endometriosis and uterine myomas and to induce abortions. It has been found to act as a glucocorticoid receptor antagonist at higher doses. It is typically started at 300 mg daily and titrated up to 1200 mg daily. The dose adjustment is based on metabolic parameters (eg, glucose) given that ACTH and cortisol levels increase as a result of glucocorticoid receptor blockade. Side effects include adrenal insufficiency, fatigue, nausea, headache, hypokalemia, edema, and endometrial thickening in women. Given that cortisol levels are not low, a high degree of clinical suspicion is necessary to identify adrenal insufficiency in patients using mifepristone. A dexamethasone dose of 2 to 4 mg daily for every 300 mg of mifepristone is recommended in patients with suspected adrenal insufficiency associated with glucocorticoid receptor antagonism.

4. NELSON SYNDROME

The clinical appearance of an ACTH-secreting pituitary adenoma following bilateral adrenalectomy as initial therapy for Cushing disease was first described by Nelson and coworkers in 1958. However, with the evolution of pituitary microsurgery as the initial therapy for Cushing disease, the Nelson syndrome is now an unusual occurrence.

Pathogenesis

It now seems likely that Nelson syndrome represents the clinical progression of a preexisting adenoma after the restraint of hypercortisolism on ACTH secretion and tumor growth is removed. Thus, following adrenalectomy, the suppressive effect of cortisol is no longer present, ACTH secretion increases, and the pituitary adenoma may progress.

Incidence

Prior to the development of transsphenoidal surgery, when bilateral adrenalectomy was the initial therapy for Cushing disease, the incidence of Nelson syndrome ranged from 10% to 78% depending on what criteria were used for diagnosis (see Chapter 9). In one series, approximately 30% of patients adrenalectomized for Cushing disease developed classic Nelson syndrome with progressive hyperpigmentation and an obvious ACTH-secreting tumor; another 50% developed evidence of a microadenoma without marked progression; and about 20% never developed a progressive tumor. The reasons for these differences in clinical behavior are uncertain. Prophylactic pituitary radiotherapy is controversial. At present, when adrenalectomy is utilized only in those patients who fail pituitary microsurgery, the incidence of Nelson syndrome is less than 10%. Nevertheless, continued examination, including plasma ACTH levels and MRI, is required following bilateral adrenalectomy in patients with Cushing disease.

Clinical Features

The pituitary tumors in patients with classic Nelson syndrome can be among the most aggressive and rapidly growing of all pituitary tumors. These patients present with hyperpigmentation and with manifestations of an expanding intrasellar mass lesion. Visual field defects, headache, cavernous sinus invasion with extraocular muscle palsies, and even malignant changes with local or distant metastases may occur. Pituitary apoplexy may also complicate the course of these tumors.

Diagnosis

Plasma ACTH levels are markedly elevated, usually over 1000 pg/mL (222 pmol/L) and often as high as 10,000 pg/mL (2220 pmol/L). MRI defines the extent of the tumor.

Treatment

Pituitary surgery by the transsphenoidal approach is the initial mode of treatment. Complete resection is usually not possible, because of the large size of these tumors. Conventional radiotherapy or gamma knife radiosurgery is employed postoperatively in patients with residual tumor or extrasellar extension.

5. THYROTROPIN-SECRETING PITUITARY ADENOMAS

TSH-secreting pituitary adenomas are rare tumors manifested as hyperthyroidism with goiter in the presence of elevated TSH. Patients with TSH-secreting tumors are often resistant to routine ablative thyroid therapy, requiring large, often multiple doses of ^{131}I and several operations for control of thyrotoxicosis. Histologically, the tumors are chromophobe adenomas. They are often very large and cause visual impairment, which alerts the physician to a pituitary abnormality. Patients with these tumors do not have extrathyroidal systemic manifestations of Graves disease such as ophthalmopathy or dermopathy.

The diagnosis is based on findings of hyperthyroidism (elevated T_4 or T_3) with elevated serum TSH and alpha subunit, and neuroradiologic studies consistent with pituitary tumor. The differential diagnosis includes those patients with primary hypothyroidism (thyroid failure) who develop major hyperplasia of pituitary thyrotrophs and lactotrophs with sellar enlargement and occasional suprasellar extension. These patients can be identified by symptoms of hypothyroidism and low thyroid hormone levels. Thyroid hormone resistance may be more difficult to exclude as T_4 and T_3 levels can also be elevated. These patients, however, tend to be clinically euthyroid or hypothyroid, have a family history of thyroid hormone resistance, and generally do not present with sellar masses. Alpha subunit levels in these patients are usually not elevated.

Treatment should be directed initially at the adenoma via the transsphenoidal microsurgical approach. However, additional therapy is usually required because of the large size of these adenomas.

Somatostatin analogs normalize TSH and T_4 levels in more than 70% of these patients when given in doses similar to those used for the treatment of acromegaly (see discussion earlier). Shrinkage of the tumor has been observed in about 40% of patients.

If tumor growth and TSH hypersecretion cannot be controlled by surgery and somatostatin analogs, the next step is pituitary irradiation. In addition, such patients may also require ablative therapy of the thyroid with either ^{131}I or surgery to control their thyrotoxicosis.

6. GONADOTROPIN-SECRETING PITUITARY ADENOMAS

Although many pituitary adenomas synthesize gonadotropins (especially FSH) and their subunits, only a minority of these patients has elevated serum levels of FSH or LH. The majority of these tumors produce FSH and the alpha subunit, but tumors secreting both FSH and LH and a tumor secreting only LH have been described.

Gonadotropin-secreting pituitary adenomas are usually large chromophobe adenomas presenting with visual impairment. Most patients have hypogonadism and many have panhypopituitarism. Hormonal evaluation reveals elevated FSH in some patients accompanied by normal LH values. Basal levels of the alpha subunit may also be elevated. The presence of elevation of both FSH and LH should suggest primary hypogonadism. TRH stimulation leads to an increase in FSH secretion in 33% and an increase in LH-β in 66% of patients.

Therapy for gonadotropin-secreting adenomas has been directed at surgical removal. Because of their large size, adequate control of the tumor is difficult to achieve, and radiotherapy is usually required.

7. ALPHA SUBUNIT-SECRETING PITUITARY ADENOMAS

Excessive quantities of the alpha subunit of the glycoprotein pituitary hormones have been observed in association with the hypersecretion of many anterior pituitary hormones (TSH, GH, PRL, LH, FSH). However, pure alpha subunit hypersecretion has been identified in several patients with large invasive chromophobe adenomas and partial panhypopituitarism. Thus, the determination of the alpha subunit may be a useful marker in patients with presumed "nonfunctioning" pituitary adenomas.

8. NONFUNCTIONAL PITUITARY ADENOMAS

"Nonfunctional" chromophobe adenomas once represented approximately 80% of all primary pituitary tumors; however, with clinical application of sensitive immunoassays of anterior pituitary hormones, these tumors currently account for a minority of all pituitary adenomas and many exhibit histochemical staining for hormones. Thus, the great majority of these chromophobe adenomas have now been documented to be PRL-secreting; a smaller number secrete TSH or the gonadotropins.

Nonfunctional tumors are usually large when the diagnosis is established; headache and visual field defects are the usual presenting symptoms. However, endocrine manifestations are usually present for months to years before the diagnosis is made, with gonadotropin deficiency being the most common initial symptom. Hypothyroidism and hypoadrenalism are also common, but the symptoms are subtle and may be missed.

Evaluation should include MRI and visual field testing; endocrine studies should include assessment of pituitary hormones and end-organ function to determine whether the adenoma is hypersecreting or whether hormonal replacement is needed.

Because these tumors are generally large, both surgery and radiation therapy are usually required to prevent tumor progression or recurrence. In the absence of an endocrine index of tumor hypersecretion such as PRL excess, serial scans at yearly intervals are required to assess the response to therapy and to detect possible recurrence.

9. PITUITARY CARCINOMA

Pituitary carcinomas are extremely rare with fewer than 200 cases reported and defined by the distant metastases of a pituitary tumor. Most present as hormone-producing invasive macroadenomas with symptoms of mass effect. ACTH- and PRL-secreting tumors are most common. Metastases may present many years after diagnosis of the primary pituitary tumor. Survival rates are low, and treatment may include additional surgery, radiotherapy, or chemotherapy (eg, temozolomide).

The Posterior Pituitary (Neurohypophysis)

Alan G. Robinson, MD

ACTH	Adrenocorticotropic hormone		**PAVP**	Plasma vasopressin concentration
ADH	Antidiuretic hormone		**pOsm**	Plasma osmolality
AIDS	Acquired immunodeficiency syndrome		**SIADH**	Syndrome of inappropriate antidiuretic hormone secretion
AVP	Arginine vasopressin			
CSW	Cerebral salt wasting		**V$_{1-3}$**	Vasopressin receptor, types 1-3
DDAVP	Desamino, D-8 arginine vasopressin			

PHYSIOLOGY OF HORMONE FUNCTION

Vasopressin is the water-retaining hormone in all mammals and along with thirst is the primary regulator of osmolality. Pressure and volume are primarily regulated by changes in sodium balance mediated via renin, angiotensin, and aldosterone. The relative importance of vasopressin in regulation of osmolality versus regulation of pressure is reflected in the sensitivity to changes in osmolality versus changes in pressure/volume. Figure 5–1 illustrates the exquisite sensitivity of the osmoreceptors to as little as a 1% change in osmolality. The regulation of vasopressin secretion by baroreceptors, however, involves many concurrent and synergistic sympathetic inputs, and a decrease in volume or pressure of 10% to 15% is necessary before there is a measurable increase in plasma vasopressin.

The exquisite sensitivity in the relation of plasma osmolality to urine osmolality and urine volume is illustrated in Figure 5–2. While the normal range of plasma osmolality encompasses a range of approximately 10 mOsm/L, for any individual, the set-point is much more narrow. Small changes in osmolality produce a corresponding and linear change in plasma vasopressin. As illustrated in Figure 5–2, the normal range of plasma osmolality and plasma vasopressin produces a corresponding linear increase in urine osmolality from maximally dilute to maximally concentrated. This entire range from maximally dilute urine to maximally concentrated urine is accomplished by a narrow range of plasma vasopressin (from approximately 1 to 5 pg/mL). In unusual circumstances, plasma osmolality can rise higher than the normal range, and there

is a corresponding increase in plasma vasopressin, but urine osmolality plateaus at the concentration of the renal inner medulla. When urine in the collecting duct is iso-osmotic with the urine in the inner medulla, maximum urine concentration is achieved. While the relation of plasma osmolality, plasma vasopressin, and urine osmolality are linear, the relation of these to urine volume is not linear. Rather, there is a logarithmic relationship between urine volume and urine osmolality. The total urine volume required to excrete a fixed quantity of urine osmolytes changes relatively little until plasma vasopressin and urine concentration are nearly absent, then urine volume increases dramatically from a few liters per day to 18 to 20 L/d for adults (10 L/m^2).

Also as illustrated in Figure 5–2, thirst has a higher threshold for stimulation than the threshold for vasopressin. This is essential for normal physiology so people can tolerate modest dehydration before becoming thirsty and do not require constant ingestion of fluid.

In the kidney, fluid is conserved by reabsorption of sodium and fluid in the proximal and the distal tubules and then reabsorption of water in the collecting duct. The counter-current multiplier system in the loop of Henle generates a high osmolality in the renal medulla. Vasopressin acts on V$_2$ receptors in principal cells in the collecting duct to stimulate the expression of intracellular water channels, aquaporin-2. When vasopressin binds to the V$_2$ receptor, adenylate cyclase is activated to produce cyclic AMP which stimulates both the production of new aquaporin-2 protein and the transfer of existing aquaporin-2 from the cytoplasm into the cell membrane. In the cell membrane, aquaporins act as water
FIGURE 5–1 Vasopressin secretion in response to percentage increases in osmolality or decreases in pressure or volume. (Reproduced with permission from Brenner BM, Rector FC. *The Kidney*. 3rd ed. Philadelphia: WB Saunders; 1986.)

channels in the hydrophobic lipid bilayer so that water moves down the osmotic gradient from the collecting duct into the principal cell. Aquaporins-3 and -4 are involved in moving water out of the principal cell into the medullary extracellular fluid and from there into the circulation. In response to changes in vasopressin, aquaporin-2 can be quickly shuttled in and out of the membrane producing rapid changes in water reabsorption and concentration of urine.

Volume/pressure regulation by vasopressin operates through V_1 receptors on blood vessels. When blood pressure is low and volume is low, activation of V_1 receptors cause contraction of vascular smooth muscle to raise blood pressure and constrict intravascular volume around the available fluid volume.

V_2 receptors also stimulate antihemophilic and von Willebrand factors. There is a third type of receptor (V_3) on anterior pituitary cells that stimulates ACTH. These functions are not further considered in this chapter.

In most physiologic situations, changes in osmolality and volume are additive or synergistic in producing the appropriate physiologic response. For example, most cases of dehydration result in greater loss of water than solute. This produces an increase in plasma osmolality and a decrease in volume that act together to stimulate thirst and the secretion of vasopressin, which promotes retention of water. Similarly, excess ingestion of hypotonic fluid produces a decrease in plasma osmolality and an increase in plasma volume, both of which decrease plasma vasopressin and result in excretion of dilute urine. The normal regulation of osmolality is an elegant and simple system. Fluid ingested and water produced from metabolized food is in excess of true
FIGURE 5–2 Normal physiologic relationship between plasma osmolality (pOsm; mOsm/kg H_2O), plasma vasopressin (PAVP; pg/mL), urine osmolality (uOsm; mOsm/kg H_2O), and urine volume (L/d). **(A)** Changes in osmolality induce linear changes in vasopressin with a normal physiologic range of osmolality producing vasopressin levels of 0.5 to 5 pg/mL. **(B)** The physiologic range of vasopressin produces linear changes in urine osmolality. At vasopressin levels above 5 to 6 pg/mL, urine osmolality is at the maximum, determined by the osmolality of the inner medulla of the kidney. **(C)** Assuming a constant osmolar load, the relationship of volume to urine osmolality is logarithmic. The urine volume to excrete a given osmolar load at the urine osmolality in **(B)** is indicated in **C**. (Data from Robertson GL, Shelton RL, Athar S. The osmoregulation of vasopressin. *Kidney Int*. 1976 Jul;10(1):25-37. Copyright 2003, A.G. Robinson, University of California at Los Angeles.)

need. The retained water causes a small decrease in plasma osmolality with a small decrease in vasopressin and excretion of the ingested fluid. If the water intake is not sufficient to supply body needs, plasma osmolality rises, producing concentrated urine to reduce fluid loss, and stimulates thirst that induces drinking to replenish body fluid.

Young infants get all or most of their calories in fluid and they do not dilute their urine as well as adults, so they are at risk to handle excess fluids. Fluid and electrolyte balance is not well regulated in elderly people. By age 80, total body water declines to as low as 50% of the level in normal young adults. Older subjects may have a decrease in glomerular filtration rate, and the collecting duct is less responsive to vasopressin. Numerous studies have indicated a decreased thirst with dehydration in elderly subjects, but also a lessened ability to excrete a water load. These age-related changes in body fluid and renal function predispose elderly people to both hypernatremia and hyponatremia. Elderly people are also more likely to have comorbid diseases that enhance their tendency to become hyponatremic or hypernatremic. It is incumbent upon the physician to pay special attention to fluid balance in children and older people.

ANATOMY OF HORMONE SYNTHESIS AND RELEASE

The posterior pituitary (unlike the anterior pituitary) is not a gland but only the distal axon terminals of the hypothalamic magnocellular neurons that make up the neurohypophysis. The cell bodies of these neurons are located in paired supraoptic nuclei and paired paraventricular nuclei of the hypothalamus. The paraventricular nuclei are located on each side of the third ventricle and axons from these neurons trace laterally and anteriorly to the location of the magnocellular neurons of the supraoptic nucleus just lateral to and above the optic chiasm. Axons of the supraoptic nucleus join axons of the paraventricular nucleus and course to the basal hypothalamus where they join the axons from the other side and course through the infundibular stalk to the axon terminals in the posterior pituitary.

The anatomic location of the physiologic regulators of osmotic and pressure/volume (baroreceptor) are located in vastly different sites. Osmoreceptors that control both thirst and osmotic regulation of vasopressin are located in the hypothalamus just anterior to the third ventricle, so the entire regulation of osmotic-induced changes in thirst and vasopressin secretion resides in a small and discrete area in the hypothalamus. Increases in osmolality stimulate the osmoreceptor to send positive signals to stimulate thirst and to release vasopressin. For volume and pressure regulation, the receptors are located in the chest. There are high-pressure arterial baroreceptors in the carotid sinus and aortic arch and low-pressure volume receptors in the atria and pulmonary venous system. The pressure/volume receptor afferent signals are carried through cranial nerves IX and X and synapse in the medulla before carrying their input to the magnocellular neurons. Both excitatory and inhibitory baroreceptor influences act on the magnocellular neurons, although some evidence indicates that a predominant mechanism involves the tonic inhibition of vasopressin secretion. A decrease in pressure/volume decreases the inhibition and stimulates release of vasopressin.

Vasopressin and oxytocin are nonapeptides that are synthesized in the cell bodies of the magnocellular neurons as part of a larger precursor molecule consisting of the hormone; a specific neurophysin; and (for vasopressin only) a glycopeptide, copeptin. Molecular weights are approximately 1000, 10,000, and 5000 daltons, respectively. Like other polypeptide hormones, the precursor proteins traverse the endoplasmic reticulum and the Golgi apparatus to be packaged in secretory granules. The neurosecretory granules then travel along microtubules down the long axons through the stalk of the infundibulum to the posterior pituitary where the granules are stored. During transport, peptide enzymes (peptidases) within the neurosecretory granules cleave the prohormone into the hormone (vasopressin or oxytocin), the carrier protein (neurophysin), and (for vasopressin) the glycopeptide. The synthesis of oxytocin and vasopressin is in separate neurons organized in clusters within the paraventricular nuclei and supraoptic nuclei. This allows stimulation of hormone specific neurons and independent release of individual hormones. The stimulus for secretion of vasopressin or oxytocin is by neurotransmitters acting on the appropriate magnocellular cell body (perikarya). An action potential propagates along the axon, causing an influx of calcium at the axon terminal that stimulates fusion of neurosecretory granules with the cell membrane and release of the content of the granules into the perivascular space.

PATHOPHYSIOLOGY

All defined pathophysiology of the posterior pituitary is related to the function of vasopressin rather than oxytocin. Both decreased function of vasopressin and increased function of vasopressin manifest as abnormalities of water balance and depend upon action of vasopressin on the V_2 receptor of the kidney rather than the V_1 vascular receptors. The clinical presentation of low vasopressin function (diabetes insipidus) or excess vasopressin function (syndrome of inappropriate antidiuretic hormone secretion [SIADH]) is determined by the physiology of thirst. In humans thirst is well regulated to increase when needed but not well regulated to decrease when not needed. When vasopressin is decreased or absent (diabetes insipidus), there is abnormal excretion of a large volume of dilute urine. This should cause hyperosmolality and an increase in serum sodium. However, as illustrated in Figure 5–2, an elevated plasma osmolality stimulates thirst, and a patient will drink a large volume of fluid to keep their sodium in the high normal range. So, the clinical presentation of decreased vasopressin is one associated with polyuria of dilute urine, together with polydipsia, but with serum sodium in the normal range. Alternatively, when vasopressin is increased, there is abnormal concentration of urine and retention of water. The volume expansion by retained water dilutes serum sodium. If thirst were inhibited by hypo-osmolality as efficiently as thirst is stimulated by hyperosmolality, then the decrease in osmolality would produce a profound decrease in fluid intake, and a normal serum sodium would

be maintained by the natural loss of fluid with perspiration, gastrointestinal fluid loss, and the urine output necessary to excrete ingested osmoles produced by food intake. Thirst, however, is not sufficiently inhibited, and the volume expansion not only dilutes serum sodium, but induces sodium excretion to reduce extracellular volume, which worsens the hyponatremia. So, the presentation of increased vasopressin is biochemically a presentation of hyponatremia. There is concentrated urine with no change in thirst, modest volume expansion, hyponatremia, and natriuresis.

The other physiologic principle that determines some of the pathophysiology of abnormal secretion of vasopressin is that while osmolality is regulated by changes in water balance, and volume is regulated by changes in sodium balance; when in conflict, volume will be preserved at the expense of osmolality. Thus, if dehydration is produced by diabetes insipidus, sodium will be retained to protect volume, even if it aggravates hypernatremia. With SIADH when sodium is diluted and extracellular volume is expanded, natriuresis is initiated to decrease extracellular volume in spite of the need to retain sodium to correct the hypo-osmolality.

DEFICIENT VASOPRESSIN: DIABETES INSIPIDUS

Diabetes insipidus is literally the excretion of a large volume of urine (diabetes) that is hypotonic, dilute, and tasteless (insipid). Patients present with polyuria. Other causes of polyuria such as osmotic diuresis that occur in diabetes mellitus or intrinsic renal disease must be excluded. Frequent urination, without an increase in urine volume, suggests a urologic abnormality. Most adults will tolerate polyuria without complaint until it exceeds 3 to 4 L/d. If polyuria is shown to be dilute, the pathophysiologic mechanisms include: (1) primary ingestion of excess fluid, (2) abnormally decreased synthesis and secretion of vasopressin, (3) increased metabolism of vasopressin, and (4) decreased end-organ response to vasopressin.

A. Ingestion of excess fluid and normal urine excretion—primary polydipsia
Primary polydipsia with ingestion of large quantities of water produces modest decreases in plasma osmolality, decreased secretion of vasopressin, and excretion of profound quantities of urine. As the volume of dilute fluid delivered to the collecting duct in adults is approximately 18 L/d (10 L/m^2), this quantity of dilute urine can be excreted on a daily basis while maintaining serum osmolality in the normal range. Virtually any pathologic process in the hypothalamus that causes diabetes insipidus may rarely cause primary stimulation of the thirst center and primary polydipsia on an organic basis. Alternatively, primary polydipsia may occur as a behavioral abnormality in psychiatric patients in whom the excess water ingestion and urination may represent delusions tied to bodily cleansing. The large volume of urine passing through the collecting duct in these patients washes urea out of the inner medulla and reduces the inner medulla osmolality. Additionally, the chronic suppression of vasopressin release and lack of action of vasopressin on the renal collecting duct decreases uptake of urea and decreases the synthesis of aquaporins in the collecting duct cells, adding to the inability to concentrate the urine maximally. Each of these abnormalities returns to normal in several days to weeks after fluid ingestion is decreased to normal.

Primary polyuria may be induced in a normal person if excess fluid is administered parenterally. This occasionally occurs in postoperative pituitary surgery and even in cases that do not involve the pituitary. In many surgical procedures, the stress of the surgery is a stimulus to release of vasopressin, and administered fluids may be retained during the procedure. Postoperatively, the stress is released, and patients have a normal diuresis of the retained fluids. If this normal excretion of fluid is matched by increased fluids administered parenterally, the patient will continue to excrete large volumes of urine. If the administered fluid is normal saline, the patients will excrete a large volume of isotonic urine. If the volume administered and subsequent urine output is sufficiently great, the patients will be unable to concentrate or dilute their urine above or below an iso-osmotic level regardless of therapeutic agents. The large osmotic load delivered to the kidney may make the patient unresponsive even to administered desmopressin, producing an iatrogenic therapeutic dilemma.

B. Abnormal synthesis and secretion of vasopressin
It is important to remember that the complaint of polyuria is based on the volume of the urine not the urinary concentration. Therefore, as evident from Figure 5–2, considerable loss of ability to secrete vasopressin can occur before there is much loss of ability to concentrate the urine and even greater loss can occur before there is a noticeable increase in urine volume.

1. GENETIC ABNORMALITIES OF NEUROHYPOPHYSEAL NEURONS

Familial hypothalamic diabetes insipidus.   Familial diabetes insipidus may be caused by an autosomal dominant mutation in the vasopressin gene. Usually the mutation involves DNA sequences in the neurophysin or signal peptide region of the precursor gene rather than the region encoding vasopressin itself. These mutations cause abnormal folding of the precursor protein, which produces abnormal trafficking and accumulation of a mutant prohormone in the endoplasmic reticulum. This produces alterations in packaging of the prohormone into neurosecretory granules in the Golgi apparatus. By ill-defined mechanisms, this leads to cell death of the vasopressin-producing neurons. Because the pathology in these neurons develops over time, young children may have normal urine output, and diabetes insipidus is not expressed until late childhood. An autosomal dominant form of diabetes insipidus also occurs in association with diabetes mellitus, optic atrophy, and deafness (DIDMOAD), Wolfram syndrome. Children with midbrain malformations may have abnormal structural architecture in the hypothalamus producing diabetes insipidus and abnormalities of thirst.

2. PATHOLOGIC LESIONS OF THE NEUROHYPOPHYSIS

Solid tumors and hematologic malignancies.   The most common solid tumor to produce diabetes insipidus is craniopharyngioma. Suprasellar germinoma or pinealoma in children, which may have elevated human chorionic gonadotropin (hCG) levels and be associated with precocious puberty, commonly produces diabetes insipidus. Metastatic disease to the pituitary hypothalamic area, for example, from breast or lung cancer, is more likely to produce diabetes insipidus than a deficiency of anterior pituitary hormones because the metastases lodge in the portal system of the hypothalamus, where the vasopressin axons from the two sides join to form the pituitary stalk. Usually, there are widespread metastatic lesions elsewhere. Lymphoma or infiltration of the hypothalamus with leukemia are rare causes of diabetes insipidus.

Trauma or surgery.   The anatomy of the neurohypophyseal system aids our understanding of this pathology. Hormone synthesis and regulation of release are high in the hypothalamus. Surgery or trauma at the level of the pituitary traumatizes only the axon terminals. Trauma of the axon terminals may disrupt the release of hormone, but usually this produces only a transient inability to secrete hormone and transient diabetes insipidus. Surgery in the hypothalamic area is more likely to produce abnormal vasopressin secretion. Sectioning of the posterior pituitary stalk produces a characteristic pattern of diabetes insipidus known as the triphasic response. This is illustrated in Figure 5–3. Initial axonal shock inhibits the release of any vasopressin, and there is a period of diabetes insipidus that lasts for 5 to 10 days. Then, the severed axons in the posterior pituitary

become necrotic, and there is uncontrolled release of vasopressin. If excess fluid is administered during this time, the syndrome of inappropriate antidiuretic hormone is produced with hyponatremia (described later). This lasts for 5 to 10 days until all of the residual vasopressin leaks from the axon terminals, and there is then return of diabetes insipidus. While the classic response to stalk section is the three phases, in many clinical situations not all three phases occur. The most common occurrence after surgery in the pituitary or hypothalamus is transient diabetes insipidus that lasts a few days without subsequent sequelae. With partial damage to the pituitary stalk rather than total section, it is possible that the second phase will occur without preceding or subsequent diabetes insipidus (ie, isolated second phase). In the isolated second phase, there are sufficient normally functioning vasopressinergic neurons to avoid diabetes insipidus in the first and third phase; however, the damaged axon terminals leak vasopressin that will, when coupled with excess fluid intake, produce SIADH and hyponatremia. Characteristically, hyponatremia occurs 5 to 10 days after pituitary surgery, lasts for 5 to 10 days, and then resolves. Late occurrence of diabetes insipidus, that is, third phase without a first or second phase, is distinctly uncommon.

Closed head trauma, especially with fracture of the basal skull, may produce diabetes insipidus and the patterns above. Hypothyroidism and adrenal insufficiency both decrease water excretion and when present may mask diabetes insipidus. Normal thyroid and adrenal function must be assured in considering operative or trauma-induced diabetes insipidus, and loss of these hormones should be suspected in the decreasing urine volume interpreted as "recovery" of diabetes insipidus in this setting.

Patients with diabetes insipidus due to surgery or trauma may eventually recover. The level of section determines the number of magnocellular neurons that are actually destroyed. The higher in the stalk and the closer the section to the perikarya, the greater the number of neurons that die. Vasopressin-producing neurons whose axons terminate in the hypothalamus and serve as secretagogues for ACTH in the anterior pituitary may persist and hypertrophy after surgery or trauma. Additionally, branching of axons may develop in the hypothalamus after surgery or trauma, and these branches may generate new connections of vasopressinergic neurons to blood vessels. By these mechanisms, sufficient vasopressin function may return (usually within 1 year) to have normal fluid balance and no symptoms of diabetes insipidus.

Granulomatous and infectious disease.   Langerhans cell histiocytosis is the generic term that includes severe fulminant visceral Letterer-Siwe disease, multifocal Hand-Schuller-Christian disease, and benign eosinophilic granuloma. Diabetes insipidus is part of the central nervous system involvement in these disorders and is associated with other abnormalities of the head involving the cranial bones, oral mucosa, or brain. Systemic manifestations in the lung, bone, and skin may also be present. Wegener granulomatosis and sarcoidosis may also have diabetes insipidus as a part of the central nervous system pathology. Tuberculosis (historically) and other infections at the base of the brain may cause diabetes insipidus.

FIGURE 5–3 Illustration of the phases of urine output after section of the pituitary stalk. The *triphasic response* consists of: (1) diabetes insipidus due to axonal shock and lack of release of vasopressin; (2) an antidiuretic interphase when vasopressin leaks from the severed neurons; and (3) return of diabetes insipidus when the store of vasopressin in the posterior pituitary is depleted.

Lymphocytic infundibulohypophysitis.   It is now recognized that many cases of diabetes insipidus, that were previously termed idiopathic and for which there was no specific etiology, are probably due to lymphocytic infiltration of the neurohypophysis on an autoimmune basis. Magnetic resonance or computed tomographic imaging may reveal enlargement of the pituitary stalk as evidence of the lymphocytic invasion. There may be resolution of the autoimmune response with time, and the stalk may return to normal size, but the diabetes insipidus is usually permanent.

Essential hypernatremia—Adipsic hypothalamic diabetes insipidus.   A rare variant of diabetes insipidus involves an absent osmoreceptor function, but an intact baroreceptor function. In this form of diabetes insipidus, if patients drink they have polyuria. However, the patients do not sense thirst and, therefore, usually do not drink. Lack of fluid intake results in an elevation of serum osmolality, but osmoreceptor function is absent and does not respond to the increased osmolality by secreting vasopressin or stimulating thirst. Vasopressin synthesis and storage are normal as demonstrated by specific tests of baroreceptor function. Characteristically, these patients do not drink water and hence become sufficiently dehydrated that their baroreceptors stimulate vasopressin release; they remain in a balanced situation with an elevated serum sodium, relatively concentrated urine, and lack of thirst.

Cerebral anoxia/brain death.   Brain dead patients who are on life support often have diabetes insipidus as part of the central nervous system pathology. It is standard practice to maintain electrolyte and water balance for maximal preservation of organs for transplantation.

C.   Increased metabolism of vasopressin in pregnancy to produce diabetes insipidus   During pregnancy, there is a true resetting of the osmostat at an osmolality approximately 10 mOsm/kg H_2O less than the normal pOsm–PAVP relationship. So, in Figure 5–2 (A), the pOsm–PAVP would have the same linear relationship but would be shifted downward on the graph with the increase in PAVP beginning at pOsm of 270. Both increases and decreases in plasma vasopressin occur at the lower pOsm while the uOsm and Urine volume response to PAVP remains the same. There is a similar change in the regulation of plasma volume. In normal pregnancy, total body water is increased by 7 to 8 L as a result of profound vasodilatation. This expanded volume is also sensed as normal with vasopressin increasing and decreasing around this new volume. Chorionic gonadotropin (hCG) and relaxin, which are produced in pregnancy, are the mediators of these effects. In pregnancy the placenta produces an enzyme, cysteine aminopeptidase, that is known as oxytocinase but similarly degrades vasopressin. Therefore, vasopressin metabolism is increased in pregnancy, markedly so from 20 to 40 weeks of gestation.

Because of the reset osmostat, a "normal" serum sodium during pregnancy may represent dehydration. There are two types of diabetes insipidus that are associated with pregnancy. In the first, the patient has a preexisting limitation of vasopressin function such as partial hypothalamic diabetes insipidus or mild nephrogenic diabetes insipidus. The ability to concentrate the urine may be limited but sufficient to maintain acceptable urine volume prepartum. During pregnancy the metabolism of vasopressin is accelerated. With increased metabolism of vasopressin, these patients may then not have sufficient concentrating ability to maintain an acceptable urine volume (see vasopressin–volume relationships in Figure 5–2) and manifest diabetes insipidus. When the pregnancy ends, PAVP is again sufficient so that the patient reverts to the existing asymptomatic condition. A second form of diabetes insipidus occurs when the level of cysteine aminopeptidase is extraordinarily higher than in normal pregnancy and produces diabetes insipidus in a patient with normal pituitary and renal function. There may be other associated pathology with the latter disease such as preeclampsia, fatty liver, and coagulopathies. Diabetes insipidus in this situation also abates when the pregnancy ends and may not recur with subsequent pregnancies.

D.   Decreased end organ response to vasopressin—nephrogenic diabetes insipidus

1. **Congenital nephrogenic diabetes insipidus**   There are two causes of congenital nephrogenic diabetes insipidus: (1) an X-linked recessive mutation of the V_2 receptor, which accounts for 90% of the cases; and, (2) an autosomal recessive mutation of the aquaporin-2 water channels. The X-linked disorder, of course, only occurs in males while disease due to mutations of the aquaporin-2 gene occurs in males and females. Female carriers of the X-linked V_2 receptor abnormality usually have no clinical disease nor do heterozygote carriers of the recessive aquaporin-2 mutations. Nephrogenic diabetes insipidus due to aquaporin-2 defects is produced when the child inherits a mutated gene from each parent that carries the recessive mutation.

    Regardless of etiology, the presentation of nephrogenic diabetes insipidus usually occurs in the first week of life presenting with vomiting, constipation, failure to thrive, fever, and polyuria. The patients are found to be hypernatremic with low urine osmolality. When measured, vasopressin levels are elevated. Immediate treatment is essential for normal neurologic development.

2. **Acquired nephrogenic diabetes insipidus**   The ability to produce concentrated urine depends upon hyperosmolality of the inner medulla which in turn requires normal kidney architecture with descending and ascending limbs of the loop of Henle, normal sodium transport, functional aquaporins, and intact long loop vascular structures (vasa recta) so that the hyperosmolality in the inner medulla is not washed away by normal blood flow. One form of nephrogenic diabetes insipidus is produced by renal disease that distorts the vascular architecture of the kidney and washes out the inner medulla; for example, polycystic renal disease, infarcts, sickle cell anemia, and so forth. The polyuria associated with potassium deficiency and hypercalcemia are both associated with decreased expression of aquaporin-2. Among drugs that may produce nephrotoxicity, the most common to produce nephrogenic diabetes insipidus are lithium (commonly when used to treat bipolar affective disorders) and demeclocycline.

DIAGNOSTIC TESTS OF DIABETES INSIPIDUS

One can determine whether there is true polyuria by measuring the 24-hour urine output, but collecting this large volume is inconvenient. Alternatively, the patient can keep a diary, recording the time and volume of each voided urine without saving the urine for examination.

A. Dehydration test   After other causes of polyuria are eliminated, the diagnosis of diabetes insipidus is accomplished by some form of dehydration test. If the patient is dehydrated when first seen and the urine osmolality is low, the "test" has been done. Plasma vasopressin is measured but the specific testing described later is not necessary. When indicated, a dehydration test should be done in a controlled environment. The description here is for adults. Dehydration of children requires special attention and should only be done by a pediatrician. Dehydration tests should not be done in infants. The patient is weighed at the beginning of the test, and a serum sodium concentration and plasma osmolality are obtained. Nothing is allowed by mouth, and the volume and osmolality of each voided urine is recorded. The patient is weighed after each liter of urine is excreted. When two consecutive measures of urine osmolality differ by less than 10% and the patient has lost 2% of his body weight, the serum sodium concentration and plasma osmolality are again determined, and a blood sample is drawn for a determination of plasma vasopressin. In the original description the patient was then given 5 units of aqueous vasopressin parenterally, although now it is often 2 μg of desmopressin, a synthetic analogue of vasopressin described later. Urine osmolality and output are recorded for an additional 2 hours. (Note that pediatricians do not use desmopressin and use a lower dose of vasopressin in this test to avoid hyponatremia.) The duration of the test varies, but in most patients a plateau in the urine osmolality will be reached by 18 hours. The test is discontinued if the patient loses 3% of the body weight. The different responses to this testing in adults are depicted in Figure 5–4. Blood is drawn to measure plasma vasopressin, and the response to administered vasopressin or desmopressin is determined.

Patients with primary polydipsia are distinguished from diabetes insipidus by the concentration of the urine at a plateau which is frequently 500 to 700 mOsm/kg, which is less than normal maximum, and by the lack of further response to administered desmopressin. Patients with hypothalamic diabetes insipidus have undetectable or low plasma vasopressin levels at the end of dehydration, minimal concentration of the urine, and a significant increase in urine osmolality to administered desmopressin, at least 50% but often 200% to 400%. Patients with nephrogenic diabetes insipidus do not concentrate their urine similar to hypothalamic diabetes insipidus, but the levels of plasma vasopressin are high, often greater than 5 pg/mL at the end of the test. Additionally, there is no further increase in urine osmolality after the administration of desmopressin. Occasionally, patients with partial hypothalamic diabetes insipidus concentrate their urine minimally with dehydration, but their maximum urinary concentration
FIGURE 5–4   Urine osmolality during a dehydration test followed by administration of desmopressin to differentiate various types of diabetes insipidus and primary polydipsia as described by Miller et al. (Miller M, Dalakos T, Moses AM, Fellerman H, Streeten D. Recognition of partial defects in antidiuretic hormone secretion. *Ann Int Med*. 1970;73:721.) See text for discussion of the differential diagnosis based on the plateau of urine osmolality with dehydration and subsequent response to administered desmopressin (or vasopressin, see text).

is not achieved, and there is an additional boost with administered desmopressin. This pattern can be similar to some patients with primary polydipsia who achieve a plateau level of urine osmolality before reaching their maximum attainable urine osmolality and show a boost in urine osmolality in response to desmopressin. These patients are usually distinguished by their response to desmopressin over time, which should be considered a continuation of the diagnostic test. Patients with partial hypothalamic diabetes insipidus decrease their urine volume and their thirst while those with primary polydipsia may continue to drink excessive amounts of water and develop hyponatremia.

Measurement of plasma vasopressin by clinically available assays is only of help in distinguishing nephrogenic diabetes insipidus (in which the level will be unequivocally elevated) from other causes of diabetes insipidus. Recent reports have described a radioimmunoassay of copeptin, the inactive carboxy peptide that is cleaved from the provasopressin molecule and secreted with vasopressin and neurophysin. The clinical usefulness of this measure is under investigation.

B. Imaging in diabetes insipidus   Imaging of the hypothalamus is an important diagnostic tool in diabetes insipidus. The exquisite sensitivity of the kidney to vasopressin, especially with regard to urine volume, determines that even 10% of the vasopressin neurons may be sufficient to maintain homeostasis without symptoms. Because of the wide anatomic distance between the paraventricular and supraoptic nuclei, tumors that

produce diabetes insipidus are either sufficiently large to destroy 90% of the vasopressin neurons or, most commonly, are located just above the diaphragma sella where the neurohypophyseal tracts of the two sides converge as they enter the pituitary stalk. Small tumors of the anterior pituitary confined to the sella are never the cause of diabetes insipidus. On T1-weighted images, the normal posterior pituitary appears as a bright spot on MRI studies. The bright spot is produced by the stored hormone in the posterior pituitary. Most normal subjects have the bright spot, although it decreases with age, and most patients with diabetes insipidus do not have a bright spot. An MRI may reveal thickening of the stalk and absence of the posterior pituitary bright spot. This is a characteristic finding of lymphocytic infundibulitis and of some granulomatous diseases. The latter prompts a search for granulomatous disease elsewhere in the body.

TREATMENT OF DIABETES INSIPIDUS

As noted earlier, adults with intact thirst mechanisms usually drink sufficient fluid to maintain serum sodium levels in the normal range. Babies and adults without access to fluid or patients who are unconscious may not drink and can develop severe dehydration and hypernatremia. Many pathologic entities that damage the hypothalamus and cause diabetes insipidus, for example, lymphocytic hypophysitis, granulomatous disease, metastatic disease, will be treated, but rarely does successful treatment of the underlying disease produce remission of the diabetes insipidus.

Hypothalamic diabetes insipdus is best treated by the vasopressin analogue desmopressin (desamino, D-8 arginine vasopressin, DDAVP). In desmopressin, the amine at position 1 is removed, increasing the half-life of the compound, and at position 8, L-arginine is changed to D-arginine, markedly reducing the pressor activity. Thus, the agent is highly selective for the V_2 receptor and based on dose and duration produces nearly 2000 times more antidiuresis than does the naturally occurring L-arginine vasopressin. Desmopressin is available as tablets (0.1 and 0.2 mg), a solution for nasal installation (100 μg/mL), a parenteral solution (4 μg/mL) and in Europe DDAVP Melt, an oral lyophilisate (60, 120, and 240 μg). There is considerable individual variability in the duration of action of desmopressin, so the dosing should be adjusted for each individual. Usually, a satisfactory schedule can be achieved with 2 to 3 tablets per day or one to two intranasal doses. A parenteral preparation can be given intravenously, intramuscularly, or subcutaneously and is 5 to 20 times more potent than the intranasally administered dose. The drug is expensive, and in many patients, a smaller dose given more frequently is more cost-effective. Other agents that prolong the action of vasopressin or the release of vasopressin include chlorpropamide, carbamazepine, clofibrate, and indomethacin, but these are off-label uses and not first-line therapies. Desmopressin is the only therapeutic agent recommended for treatment of diabetes insipidus in pregnancy because desmopressin is not destroyed by cysteine aminopeptidase and has minimal oxytocic activity on the uterus.

In patients with inadequate thirst, the best treatment is continuous administration of desmopressin to maintain a concentrated urine and then rigid adjustment of the amount of fluid that must be taken every 6 to 8 hours to maintain normal serum sodium.

In nephrogenic diabetes insipidus, any offending drug or electrolyte abnormality that might produce acquired nephrogenic diabetes insipidus should be stopped or corrected. In congenital nephrogenic diabetes insipidus, therapy is aimed at reducing urine volume through a low sodium diet and a thiazide diuretic. This causes a natriuresis which produces some contraction of the extracellular fluid volume, decreased glomerular filtration rate, decreased delivery of fluid to the collecting duct, and a decreased urine volume. Amiloride is especially recommended in this setting because it is potassium-sparing. Amiloride may also have some advantage in lithium-induced nephrogenic diabetes insipidus because amiloride decreases lithium entrance into cells in the distal tubule. Indomethacin has an antidiuretic action that especially prolongs the action of vasopressin and administered desmopressin. It also decreases urine volume in nephrogenic diabetes insipidus, but there is concern about gastrointestinal bleeding.

When diabetes insipidus occurs in patients who also have anterior pituitary deficiency, adequate treatment with thyroid hormone and hydrocortisone is essential to maintain normal renal response to desmopressin. Clinical situations such as surgical procedures, treatments that require a saline diuresis, and periods when patients are not allowed fluids by mouth require careful balance of antidiuretics (often a low dose of vasopressin by infusion), administered fluid, and sodium.

EXCESS VASOPRESSIN: SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Excess vasopressin becomes a clinical problem when there is concurrent retention of water producing hypo-osmolality. Hypo-osmolality is common in hospitalized patients but in most cases is due to underlying illness. Statistically, hyponatremia is associated with increased morbidity and mortality because it is a measure of the severity of the underlying illness. This chapter focuses on cases in which inappropriately elevated vasopressin and water retention are the cause of the hypo-osmolality (see also Chapter 21: Humoral Manifestations of Malignancy).

The differential diagnosis of hypo-osmolality is based on measuring the serum sodium concentration and estimating the extracellular fluid status. Sodium is the major cation of the extracellular fluid, and potassium is the major cation of the intracellular fluid. Water moves freely between the intracellular and extracellular fluid, so osmolality is always equivalent in both compartments. The relative balance between solute depletion and water retention as a cause of hypo-osmolality is complex, but in virtually all cases of clinically significant hypo-osmolality, there is some element of impaired water excretion and/or excessive water intake.

Plasma osmolality can be measured directly by freezing point depression or vapor pressure of plasma, but usually, hypo-osmolality is brought to clinical attention because of decreased

concentration of sodium rather than measure of osmolality. In the extracellular fluid, the major contributions to osmolality are sodium, glucose, and blood urea nitrogen (BUN). A calculated osmolality usually correlates well with measured osmolality.

$$\text{Plasma osmolality (mOsm/kg H}_2\text{O)}$$
$$= 2 \times [\text{Na}^+] \text{ (mEq/L)} + \text{Glucose (mg/dL)}/18$$
$$+ \text{BUN (mg/dL)}/2.8$$

Occasionally, when the serum sodium concentration is measured by flame photometry the measured sodium is artifactually low because flame photometry calculates the sodium in a fixed volume of plasma. If a large proportion of the plasma volume is taken up by extremely elevated levels of lipid or protein, sodium determined by flame photometry is low. Plasma osmolality determined by freezing point or vapor pressure is a direct measure of particles in solution and will be normal in these situations. So the low level of sodium by flame photometry is referred to as pseudo-hyponatremia. Hyperglycemia will produce hyponatremia because of the shift of water from the intracellular fluid to the extracellular fluid; however, the calculated osmolality will be normal. The serum sodium can be corrected for the glucose elevation by adding 1.6 to 2.4 mEq/L for each 100 mg/dL increase in serum glucose.

When true hypo-osmolality is found to exist, the differential diagnosis is of hyponatremia as illustrated in Table 5–1. The disorder is divided into four major subgroups based on the extracellular fluid volume status and the measured urinary sodium. Extracellular fluid volume status may be determined by central venous pressure, BUN/creatinine, hematocrit, or plasma protein concentrations, but usually is estimated by physical examination. If the patient is dehydrated and the urinary sodium is low, this indicates normal physiologic response to extra-renal sodium loss such as vomiting or diarrhea with continued intake of water. This is the most common cause of hyponatremia in children. The appropriate therapy is to replace the sodium and fluid deficiency with normal saline. If the patient is dehydrated but the urinary sodium is increased, this indicates a renal loss of sodium inappropriate to the decreased volume and hyponatremia. This may be due to intrinsic renal disease, diuretic use, aldosterone deficiency

TABLE 5–1 Differential diagnosis of hyponatremia.

Volume	Urine Na$^+$	Diagnosis
Low (evidence of dehydration)	<20 mEq/L	Category 1: Total body Na$^+$ depleted, normal renal response (eg, hemorrhage, GI losses)
	>25 mEq/L	Category 2: Renal Na$^+$ loss (eg, renal disease, diuretics, CSW Addison disease)
Normal or expanded (edema may be present)	<20 mEq/L	Category 3: Hyperaldos teronism secondary to inadequate perfusion (eg, CHF ascites, etc)
	>40 mEq/L	Category 4: SIADH-Na$^+$ loss secondary to volume expansion

Copyright 2005, A.G. Robinson, University of California at Los Angeles.

(see discussion of Addison disease in Chapter 9), or cerebral salt wasting (CSW) (to be discussed later). Appropriate therapy is to replace the sodium and fluid loss with normal saline but also with appropriate treatment of the underlying defect. If the extracellular fluid volume is expanded with edema or ascites and the urinary sodium is low, this indicates hyperaldosteronism, secondary to reduced or ineffective plasma volume as in cirrhosis or congestive heart failure, and the appropriate therapy is treatment of the underlying condition. Where the extracellular fluid volume appears to be normal with increased urinary sodium, this indicates the pathophysiology of inappropriate secretion of antidiuretic hormone. Note that the urine osmolality will not be maximally dilute and that measured vasopressin will not be maximally suppressed in any of the four categories in Table 5–1. Although not appropriate to the osmolality, in the first three categories, the elevation of vasopressin is appropriate to the real or perceived decreased plasma volume. It is only in the fourth category (SIADH) that vasopressin is inappropriate both for plasma volume and osmolality. Copeptin, the inactive glycopeptide that is cleaved from the provasopressin molecule and secreted with vasopressin and neurophysin, was mentioned earlier. Some studies have indicated that measurement of levels of this peptide might be useful in evaluating various causes of hyponatremia.

A. The pathophysiology of the hyponatremia in SIADH   The pathophysiology of SIADH begins with uncontrolled secretion of vasopressin. Thirst is not adequately suppressed so fluid intake continues. This produces volume expansion and hyponatremia in the sequence illustrated in Figure 5–5. Vasopressin limits the excretion of water in the urine. Continued ingestion of water (**part A**) produces an expansion of extracellular and intracellular volume. The body attempts to bring the extracellular fluid volume back to normal by natriuresis (**part B**) of isotonic urine. The mechanism of natriuresis is complex and involves increased glomerular filtration; pressure natriuresis; and natriuretic factors, especially atrial natriuretic peptide and brain natriuretic peptide. This natriuresis decreases total body water and total body sodium but because it is isotonic, it contributes little to the degree of hyponatremia. Next, the body attempts to return intracellular fluid volume to normal by (**part C**) excreting from the intracellular fluid potassium and organic osmolytes such as glutamine, glutamate, myoinositol, aspartate, and N-acetylaspartate. In spite of the attempt to normalize extracellular and intracellular fluid, there remains a tendency for these compartments to be slightly expanded. The last adaptation (**part D**) is caused by this tendency for volume expansion and produces changes in the kidney to make it less responsive to the chronic inappropriate excess of vasopressin and to allow an increase in water excretion. Vasopressin retains water by stimulating V$_2$ receptors on the principal cells of the collecting duct. This stimulation both increases the synthesis of aquaporin-2 molecules and the insertion of aquaporins into the cell membrane. With chronic excess of vasopressin, the density of aquaporins in the membrane increases dramatically, producing a state of chronic increase in water retention. However, in response to the chronic volume expansion (produced by the water

FIGURE 5–5 Illustration of the changes in intracellular fluid and extracellular fluid volumes in the pathophysiology of SIADH with the chronologic pattern of: **(A)** Expanded ECF and ICF volume with solute dilution. **(B)** Natriuresis to decrease ECF volume expansion. **(C)** Extrusion of intracellular potassium and osmolytes to decrease intracellular volume expansion. **(D)** Restoration of near normal volume in ECF and ICF. **(E)** Renal adaptation to allow excretion of more dilute urine in spite of excess vasopressin. (Copyright 2005, A.G. Robinson, University of California at Los Angeles.)

retention) there is by unknown mechanisms an adaptation that reduces the number of aquaporins in the principal cells. In this new state **(part E)**, ingestion of sodium will somewhat re-expand the extracellular fluid volume and be excreted, while ingestion of water will be more easily excreted because of the renal adaptation of decreased aquaporins—therefore a new steady state.

Of the diagnoses of hyponatremia shown in Table 5–1, the two categories that are most difficult to differentiate are those with elevated urinary sodium concentrations. On physical examination, it may be difficult to differentiate moderately low extracellular fluid volume from normal extracellular fluid volume. In this situation, the differential diagnosis may be aided by a volume challenge of normal saline infused at a modest rate over a few hours while following urinary and plasma sodium determinations. If the patient is in diagnostic category 4 (SIADH) and relatively equilibrated, the administered saline will be excreted so there will be an increase in urinary sodium and no change or a slight decrease in serum sodium concentration. If the patient is in category 2 with a renal loss of sodium, sodium from the administered

saline will be retained, and the water excreted will somewhat dilute urinary sodium. This will result in a decrease in urinary sodium while the serum sodium concentration will rise. This volume challenge in difficult cases is not considered therapy, but only an assist to make the appropriate diagnosis, which will then lead to the initiation of appropriate therapy.

In diagnostic category 2 (Table 5–1), there is considerable controversy regarding the diagnosis and incidence of CSW. CSW is severe primary natriuresis producing volume depletion and hyponatremia. The diagnosis is only confirmed when volume depletion can be confirmed by some combination of decreased central venous pressure, decreased plasma volume, increased BUN/creatinine, or increased hematocrit and plasma protein levels. CSW has been intensively studied as a cause of hyponatremia in subarachnoid hemorrhage. Natriuretic peptides are increased in subarachnoid hemorrhage, but they are also increased in well-documented SIADH. Measured plasma volume in subarachnoid hemorrhage is difficult to interpret because of the lack of sensitivity of readily available clinical measures. There may be both inappropriate

secretion of vasopressin and inappropriate natriuresis in these patients with the clinical presentation depending on the relative contributions of each. It is consistent that infusion of isotonic saline does not correct the hyponatremia in SIADH but may do so with CSW. The most convincing cases of CSW are those that occur in hospitalized patients in whom there is a sudden unexplained increase in urine volume (not seen in SIADH) and urine sodium excretion. This has been reported in several cases of children with traumatic brain injury or brain surgery. The acute massive diuresis and natriuresis is accompanied by definitive volume contraction by the measures listed earlier. Most of these cases respond to replacement with normal or hypertonic saline.

B. Symptoms of hyponatremia   The symptoms of hyponatremia are largely dependent on the rapidity of the development of hyponatremia. When hyponatremia develops rapidly and is severe (serum sodium level <120 mEq/L), patients are at risk for cerebral edema with herniation of the brain stem (especially children and young women). Other complications include neurogenic pulmonary edema, seizures, coma, and respiratory arrest. Hyponatremia that develops slowly over a long period of time is surprisingly well-tolerated even at very low levels of serum sodium. Neurologic symptoms usually do not occur with sodium values above 120 mEq/L, but any degree of hyponatremia might exacerbate other comorbid conditions. Hyponatremia is usually considered chronic if hyponatremia has developed slowly and persisted for greater than 48 hours.

C. Clinical syndromes of SIADH   The clinical criteria for SIADH remain those described by Bartter and Schwartz in 1967: decreased plasma osmolality; inappropriate concentration of the urine; clinical euvolemia; increased urinary sodium excretion; and absence of other causes of euvolemic hypo-osmolality such as hypothyroidism, adrenal insufficiency, or diuretic use. The three main etiologies of SIADH are ectopic production of vasopressin by cancer (see Chapter 21), drug-induced SIADH, and lesions in the pathway of the baroreceptor system, especially central nervous system disorders and pulmonary disorders. As noted earlier, the baroreceptors consist of a diffuse system of receptors in the chest and synapses in the brain. Some of the input from them is inhibitory. Lesions which disrupt the flow of signals in the lung or in the brain may decrease this inhibitory signal and produce inappropriate secretion of vasopressin. Acquired immune deficiency syndrome (AIDS) is a recognized cause of SIADH, although dehydration, adrenal insufficiency, pneumonitis, and renal tubular toxicity associated with therapy may confound the ability to make the diagnosis of SIADH an exclusive cause of the hyponatremia. Prolonged strenuous exercise (eg, marathon running) may increase secretion of vasopressin and with excessive intake of hypotonic fluid induce SIADH. A rare cause of SIADH reported in two pediatric patients is a genetic mutation of the V_2 receptor in principal cells producing unregulated activation. These patients have the manifestations of hyponatremia and SIADH but no measurable plasma vasopressin. Some elderly patients fit the criteria for SIADH without a definitive diagnosis.

TABLE 5–2   **Major etiologies of SIADH.**

Ectopic production of vasopressin by tumors
Bronchogenic carcinoma
Carcinoma of duodenum and pancreas
Ureteral, prostate, bladder carcinoma
Carcinoma of the uterus
Thymoma
Mesothelioma
Lymphoma and leukemia
Drug induced
Desmopressin and oxytocin
Chlorpropamide
Carbamazepine
Clofibrate
Ecstasy
Selective serotonin reuptake inhibitors
Tricyclic antidepressants
Monoamine oxidase inhibitors
Vinca alkaloids, cisplatin, cyclophosphamide
Disrupt neural pathways
Pulmonary disorders: pneumonia, tuberculosis, fungal infection, empyema, positive pressure ventilation
Central nervous system disorders: infection, trauma, surgery, hemorrhage, inflammatory diseases, degenerative diseases, porphyria
Nephrogenic SIADH
Extremely rare mutation of the V_2 receptor producing chronic activation
Other etiologies
AIDS
Marathon running or other strenuous exercise
Acute psychosis

Specific disorders, which have been reported to cause SIADH, are detailed in Table 5–2, but because of the diffuse regulation of the baroreceptor system and the multiple disorders that can influence vasopressin release via this system, no list should ever be considered complete. SIADH is less common in children than adults and when present is usually chronic.

TREATMENT OF HYPONATREMIA IN SIADH

The therapy of hyponatremia follows pari passu the symptoms of hyponatremia. When hyponatremia is known to have occurred rapidly and is severe and symptomatic, the patient should be treated quickly. When the onset is slow and the syndrome chronic, the treatment should be slow. Acute hyponatremia is arbitrarily defined as having developed over less than 48 hours. Usually, the serum sodium must be less than 120 mEq/L to produce symptomatology. Discontinuing the administration of any hypotonic fluid and the administration of hypertonic NaCl (eg, 3%), possibly with the addition of a diuretic, should be promptly considered. Often acute disorders occur in the hospital in a surgical or obstetrical setting and children and young women are at the greatest risk. For chronic hyponatremia, overly aggressive treatment may cause new and additional pathology. As shown in Figure 5–5 (C), tissue adaptation to chronic hyponatremia results in the loss of intracellular osmolytes.

In the brain these are the same osmolytes that would normally increase in neurons to protect brain volume from a sudden shift of intracellular fluid to the extracellular fluid when there is an acute increase in osmolality of the extracellular fluid. If during the treatment of hyponatremia in SIADH the extracellular fluid osmolality is rapidly increased, the brain has lost the ability to protect intracellular volume and water rapidly moves out of neurons. Brain shrinkage is thought to be the cause of a syndrome of myelinolysis which was first described in the pons—hence the term central pontine myelinolysis. The process can occur diffusely throughout the brain. The cause may be disruption of the blood–brain barrier and influx of plasma components that are toxic to the oligodendrocytes. The syndrome consists of neurologic deterioration over several days with fluctuating consciousness, convulsions, hypoventilation, and hypotension. Eventually, these patients may develop pseudobulbar palsy with difficulty in swallowing and inability to speak, even leading to quadriparesis. Recovery from this syndrome is variable, and many neurologic complications are permanent. MRI scans will demonstrate the demyelination, but usually not until 3 to 4 weeks after correction of the hyponatremia. Chronic alcoholics, patients with malnutrition or liver disease and patients with profound hyponatremia or hypokalemia are at increased risk to develop osmotic demyelination.

In chronic hyponatremia that is asymptomatic, the safest therapy is restriction of free water intake and slow correction of the hyponatremia over days. For chronic hyponatremia that has central nervous system symptoms, carefully controlled and limited increases in the osmolality should be undertaken. Coma or convulsions are obvious signs of neurologic symptoms that may be produced by hyponatremia, but nausea, vomiting, and confusion may be less specific signs of neurologic impairment. There is considerable debate in the literature about the exact rate of correction of the sodium concentration in these cases, and one should review the most up to date recommendations prior to initiating therapy. General parameters of therapy are that the increase of serum sodium might be accomplished at a rate of 0.5 to 1 mEq/L/h with a total correction not to exceed 10–12 mEq/L in the first 24 hours. For those at high risk for osmotic demyelinating the total should not exceed 8 mEq/L in the first 24 hours. In no case should the correction exceed 18 mEq/L in the first 48 hours. Active correction is stopped when the patient's symptoms are abolished, the serum sodium level is greater than 120 mEq/L, or the total magnitude of correction is 18 mEq. Further treatment is undertaken with fluid restriction as for asymptomatic hyponatremia. When overly rapid increases in serum sodium occur, especially in persons at high risk for osmotic demyelination, some experts have given dilute fluids, sometimes with desmopressin, to acutely re-lower the serum sodium. Benefit is supported by some animal studies, but there are no controlled studies documenting that this is beneficial in patients. Fluid intake is restricted in chronic SIADH, but salt intake is not as all of these patients have some degree of sodium loss secondary to the volume expansion and natriuresis.

The tetracycline derivative demeclocycline is known to cause nephrogenic diabetes insipidus and has been used to treat chronic SIADH. Dosages of 600 to 1200 mg/d in divided doses decrease urine osmolality (this use is off-label). Three to four days are required for the effect to reach equilibrium. Azotemia and nephrotoxicity have been reported with demeclocycline especially in patients with cirrhosis. Fluid restriction is the preferred therapy in pediatrics although in young children restricting fluids may not provide adequate calories.

Any of the therapies for hyponatremia and especially fluid restriction will reduce the extracellular fluid volume and, hence, remove the volume-mediated stimulus of renal adaptation illustrated in part D of Figure 5–5 in which the kidney becomes somewhat less responsive to the excess vasopressin by reduction in the amount of aquaporin-2 water channels. When the volume stimulus is removed, there is again an increase in the density of membrane water channels, and the kidney becomes more efficient in retaining water. This accounts for the common clinical observation that fluid restriction that is initially effective may have to be increasingly severe to maintain a beneficial effect.

The most specific treatment for SIADH is to block the V_2 receptors in the kidney. There are recently approved vasopressin receptor antagonists, vaptans, which enhance renal free water excretion (aquaresis) without sodium excretion (natriuresis). Unlike the agonist, desmopressin, these antagonists are nonpeptide drugs. Conivaptan is a combined V_{1A} and V_2 receptor antagonist that is available for intravenous administration to hospitalized patients. Tolvaptan is a selective V_2 receptor antagonist that can be administered orally and is approved to treat severe hyponatremia (serum Na <125 mEq/L) in patients who are symptomatic or patients who have failed to correct with fluid restriction. Vaptans should not be used in conjunction with other therapy, for example, hypertonic saline or fluid restriction. Clinical trials with these agents indicate that they will be useful to treat hyponatremia of SIADH and of other causes. The risk of brain myelolysis caused by too rapid correction of sodium with these agents is the same as with other therapies, so the same recommendations about rates of correction of serum sodium described earlier will apply as physicians gain further experience with these agents. There is little experience with use of vaptans in pediatrics.

SUMMARY

Table 5–3 compares and contrasts pathophysiologic entities associated with decreased vasopressin, diabetes insipidus, and excess vasopressin, SIADH.

OXYTOCIN

The anatomy and synthesis of oxytocin is similar to that described for vasopressin. While there are a number of central nervous system actions that have been attributed to oxytocin (probably acting as a neurotransmitter), the physiologic functions of this posterior pituitary hormone are limited to lactation and parturition.

A. Lactation   The hypothalamic/pituitary hormones critical to lactation are prolactin and oxytocin. Prolactin secretion from the anterior pituitary is described in Chapter 4, and its primary activity is to promote milk production. Oxytocin stimulates milk

TABLE 5–3 Comparison and contrasting the pathophysiology of DI and SIADH.

Pathophysiologic	Lack of Vasopressin: Diabetes Insipidus	Excess Vasopressin: SIADH
Urine	Dilute with increased volume—polyuria	Concentrated with decreased or normal volume
Thirst	Increased and protective—polydipsia	*Not* decreased and *not* protective—normal intake
Serum sodium	Tendency to hypernatremia, but *high normal* due to polydipsia	Decreased—hyponatremia due to water retention
Initial plasma volume	Decreased by polyuria	Increased by water retention
Urine sodium	Variable	Inappropriately elevated for hyponatremia—natriuresis induced by volume expansion
Presentation	Polyuria and polydipsia	Hyponatremia (in SIADH accompanying euvolemia and natriuresis)
Differential diagnostic considerations with the presenting symptoms and laboratory data	*Excess water intake (primary polydipsia where polyuria is normal)* *Solute diuresis producing polyuria and polydipsia, eg, diabetes mellitus*	*Renal Na$^+$ loss (diuretics, Addison disease, renal disease, cerebral salt wasting)* *Elevated urine Na$^+$, but plasma volume is low* *Volume expansion, hyperaldosteronism (CHF, ascites, etc), but urine Na$^+$ is low* *ECF loss (sweating, diarrhea), but volume is decreased and urine Na$^+$ is low*
Decreased or increased synthesis of vasopressin based on anatomy	Tumors with suprasellar origin or extension— infiltrative lesions of the basal hypothalamus—neurohypophyseal infundibulitis	Interruption of inhibitory input from baroreceptors in the chest or CNS
Decreased or increased synthesis based on genetics	Hereditary hypothalamic DI—autosomal recessive AVP gene in AVP producing neurons	Ectopic production of vasopressin by gene derepression in cancer
Disruption of normal control mechanisms	Osmoreceptor system—discrete lesions in anterior hypothalamic area decrease positive signal to AVP neurons and decrease AVP	Baroreceptor system—diffuse lesions in chest, brain stem, and hypothalamus decrease negative input to AVP neurons and increase AVP
Abnormal metabolism of vasopressin	DI in pregnancy	None
Decreased or increased response of V$_2$ receptor	Nephrogenic DI—X-linked recessive mutated inactive V$_2$ receptor	Nephrogenic SIADH—mutated activated V$_2$ receptor—*rare*—unmeasurable AVP
Decreased or increased response of aquaporins	Nephrogenic DI—autosomal recessive mutated inactive aquaporin 2	None
Diagnostic laboratory tests	Elevated pOsm with low uOsm AVP elevated in nephrogenic DI, low in other DI Masked by adrenal or thyroid deficiency, which inhibits free water excretion	Decreased pOsm with high uOsm (not maximally dilute) Urine Na$^+$ inappropriate for hyponatremia AVP elevated in SIADH but also in all differential causes of hyponatremia Normal cortisol, and thyroid and no diuretic therapy; each may cause hyponatremia
Diagnostic imaging—MRI	Head, suprasellar area, tumors, infiltrates, widened stalk, absent posterior pituitary bright spot	Chest—for any pathology, but especially for cancer; head for CNS pathology; full body for cancer
Treatment	Encourage water Diuretics cause volume contraction and reduce urine volume in nephrogenic DI Vasopressin receptor agonists—desmopressin If hypernatremic, overaggressive treatment may rapidly decrease pOsm and produce cerebral edema	Restrict water Drugs that inhibit renal action of vasopressin—demeclocycline Vasopressin receptor antagonists—vaptans Acute onset = rapid therapy Chronic disease = slow therapy Overaggressive treatment to rapidly increase serum Na$^+$ may produce osmotic demyelination

letdown associated with nursing. The milk-producing unit of the breast is the alveolar system in which clusters of milk-producing cells are surrounded by specialized myoepithelial cells. Milk is synthesized in glandular cells of the alveoli. Oxytocin receptors are localized on glandular cells and on myoepithelial cells along the duct. Oxytocin stimulates the cells along the duct to shorten and the ducts to widen, enhancing milk flow through the ducts to the nipple. Suckling at the breast stimulates mechanoreceptors or tactile receptors that ascend through the spinal cord to the lateral cervical nucleus and eventually to the oxytocinergic magnocellular

neurons in the supraoptic and paraventricular nuclei. Neurotransmitters trigger the release of oxytocin. Oxytocin is released in a pulsatile fashion producing a pumping action on the alveoli and promoting maximal emptying of milk from the alveoli. There is no evidence for a central pacemaker to regulate the secretion of oxytocin, and the mechanism of synchrony among individual oxytocinergic neurons is unknown. The importance of oxytocin in maintaining milk secretion is demonstrated in transgenic mice with a knockout of oxytocin synthesis. These animals deliver their young normally, demonstrating the redundant systems for parturition, and produce milk normally, demonstrating the role of prolactin, but are unable to release milk when the pups suckle, demonstrating the importance of oxytocin for milk letdown. The pups die of dehydration with no milk in their stomachs. Administration of oxytocin to the knockout mothers restores milk secretion, and the pups survive.

B. Parturition   Estrogen activates many events that initiate and stimulate parturition whereas progesterone inhibits these events. The uterine myometrial cells have intrinsic contraction activity and are responsive to oxytocin. During pregnancy, oxytocin is released, but oxytocinase decreases the plasma level of oxytocin, and progesterone and relaxin decrease the intrinsic contractility of the myometrium. In humans, there is a dramatic increase in uterine responsiveness to oxytocin as parturition approaches. Several hormones other than oxytocin including prostaglandins, endothelins, adrenergic agonists, corticotropin-releasing hormone, glucocorticoids, and cytokines also participate in the initiation and completion of labor. The most specific role of oxytocin may be the release of oxytocin brought about by vaginal and cervical dilatation produced by the descending head and body, known as the Fergusson reflex. This may be important in stimulating uterine muscle to contract maximally and clamp down blood vessels to decrease blood loss. It is perhaps not surprising that parturition, which is so important to survival of the species, is controlled by many different pathways of cross-stimulation and feed-forward activity. The many redundant systems ensure survival of the species. Oxytocin remains the strongest stimulant to myometrial contraction, explaining its value as a therapeutic agent in inducing parturition and the interest in oxytocin antagonists to delay parturition.

C. Other actions   Other actions of oxytocin have been described in a number of species including effects on behavior of animals, effects on feeding and satiety, response to stress, stimulation of sperm transport, effects on memory, and so forth. None of these have been documented to be physiologically important in humans.

Growth

Dennis Styne, MD

ACTH	Adrenocorticotropin hormone		**IUGR**	Intrauterine growth retardation or restriction
ALS	Acid labile subunit		**JAK-STAT**	Janus kinase-signal transducers and activators of transcription
cAMP	Cyclic adenosine monophosphate			
CPHD	Combined pituitary hormone deficiency		**LDL**	Low-density lipoprotein
EGF	Epidermal growth factor		**LH**	Luteinizing hormone
EGF-R	Epidermal growth factor receptor		**LS**	Lower segment
FGF	Fibroblast growth factor		**MC4R**	Melanocortin 4 receptor
FGF-R	Fibroblast growth factor receptor		**NSD1**	Nuclear receptor–binding SET domain protein 1
GH	Growth hormone			
GHBP	Growth hormone–binding protein		**Pit-1**	Pituitary transcription factor 1
GHRH	Growth hormone–releasing hormone		**Prop-1**	Prophet of Pit-1 homeobox 1
GHSR	Growth hormone secretagogue receptor		**PTH**	Parathyroid hormone
GnRH	Gonadotropin-releasing hormone		**PTPN11**	Protein tyrosine phosphatase nonreceptor 11
hCG	Human chorionic gonadotropin			
hCS	Human chorionic somatomammotropin		**RTA**	Renal tubular acidosis
HDL	High-density lipoprotein		**SGA**	Small-for-gestational age
HESX1	Hesx1 homeodomain		**SHOX**	Short stature homeobox
hGH	Human growth hormone		**SOD**	Septo-optic dysplasia
IGF-I	Insulin-like growth factor I		**SRIF**	Somatostatin
IGF-II	Insulin-like growth factor II		**TBG**	Thyroxine-binding globulin
IGFBP	Insulin-like growth factor–binding protein		**TRH**	Thyrotropin-releasing hormone
			TSH	Thyrotropin
IGHD	Isolated growth hormone deficiency		**US**	Upper segment

Assessment of growth in stature is an essential part of the pediatric examination. Growth is an important index of physical and mental health and of the quality of the child's psychosocial environment; chronic problems in any of these areas may be reflected in a decreased growth rate which may be a critical clue as to the age of onset of the condition. We shall consider influences on normal growth, the normal growth pattern, the measurement of growth, and conditions that lead to disorders of growth.

NORMAL GROWTH

INTRAUTERINE GROWTH

The growth of a fetus begins with a single fertilized cell and ends with differentiation into more than 200 cell types, length increasing by 5000-fold, surface area by 6×10^6-fold, and weight by 6×10^{12}-fold. This all to leads to an approximately 7 lb newborn.

Overall, the growth of the fetus is dependent on the availability of adequate oxygen and nutrition delivered by the placenta and is orchestrated by a group of growth factors, all overseen by a basic genetic plan. Genetic factors are more important early in gestation, whereas the maternal environment attains more importance late in gestation.

The classic definition of small-for-gestational age (SGA), is a birth weight two standard deviations (SDs) below the mean or below the 5th percentile for birth weight, or birth weight below 2500 g for a term infant in the United States. The term intrauterine growth retardation or intrauterine growth restriction (IUGR) is not synonymous with SGA, because IUGR refers to decreased intrauterine growth velocity noted on ultrasound. Statistics and charts showing various percentiles of weight for gestational age are available to determine which premature infants are SGA and what weights are appropriate for gestational age (AGA). About 20% of SGA infants remain short as children and adults, in contrast to appropriate-for-gestational-age premature infants, who are smaller at birth but generally experience catch-up growth in the first 2 years. Those SGA infants who do not experience catch-up growth by 2 years of age may be candidates for growth hormone (GH) therapy. Recent studies suggest that preterm, AGA babies who show poor growth in the first three postnatal months follow growth patterns similar to SGA infants; thus consideration of GH therapy may be warranted as this situation receives further study.

THE PLACENTA

The placenta influences most aspects of fetal growth, including the supply of adequate nutrition and oxygen and also acts as an endocrine organ by producing and releasing hormones and growth factors. Aberrant delivery or control of any of these factors affects fetal growth. Placental weight is usually directly related to birth weight.

CLASSIC HORMONES OF GROWTH AND FETAL GROWTH

The hormones that mediate postnatal growth do not necessarily play the same roles in fetal growth. GH is present in high concentrations in the fetus, in contrast to the limited presence of GH receptors. Although this discrepancy suggests limited activity of GH in the fetus, GH does play a role in fetal growth as reflected in the average birth weight at 1 SD below the mean in GH-deficient infants. Infants with GH resistance due to abnormal, reduced or absent GH receptors (eg, Laron syndrome) have elevated GH and low serum insulin-like growth factor (IGF)-I levels; they also have decreased birth length and weight. Thyroid hormone deficiency does not directly affect human birth weight, but prolonged gestation can be a feature of congenital hypothyroidism, and this factor will itself increase weight. Placental lactogen exerts no effect on birth size in human beings. However, the concentration of placental-derived GH (from the *GHV* gene) is significantly decreased in the serum of a pregnant woman bearing a fetus with IUGR.

GROWTH FACTORS AND ONCOGENES IN FETAL GROWTH

Oncogenes may be responsible for neoplastic growth in postnatal life, but expression of these genes is important in the normal development of many fetal organs. Remarkably, the same oncogenes that cause postnatal neoplasia are prevented from causing tumors in the normally differentiating fetus. For example, a mutation in the *von Hippel-Lindau* gene, normally acting as tumor suppressor gene, predisposes to retinal, cerebellar, and spinal hemangioblastomas, renal cell carcinomas, and pheochromocytomas, but the normal *VHL* gene is expressed in all three germ cell layers of the embryo and in the central nervous system (CNS), kidneys, testis, and lung of the fetus, playing a role in normal fetal development for this gene.

INSULIN-LIKE GROWTH FACTORS, RECEPTORS, AND BINDING PROTEINS

IGF-I in the fetus is regulated by metabolic factors other than GH, in contrast to the dependence of IGF-I generation upon GH in postnatal life. One explanation is that there are fewer GH receptors in the fetus than after birth. In the human fetus, serum GH falls during later gestation owing to maturation of central nervous system's negative control, whereas serum IGF-I and IGF-binding protein (IGFBP)-3 rise during gestation, demonstrating their independence from GH stimulation.

Studies of knockout mice, which lack various growth factors or binding proteins, indicate a role for IGF-II in growth during early gestation and one for IGF-I during later gestation. Knockout of type 1 IGF receptors leads to a more profound growth failure than is found in IGF-I knockout mice alone, suggesting that factors other than IGF-I (eg, IGF-II) exert effects on fetal growth through the type 1 receptor.

Study of transgenic mice overexpressing IGFBPs supports the concepts that excess IGFBP-1 stunts fetal growth while excess IGFBP-3 leads to selective organomegaly. For example, overexpression of IGFBP-3 in mice led to organomegaly of the spleen, liver, and heart, although birth weight was not different from that of wild-type mice.

Although controversy remains over some of the data regarding IGFs and fetal growth, a summary of the complex IGF system in the fetus, based on the evidence from various species, appears to apply to the human being as follows.

1. IGFs are detectable in many fetal tissues from the first trimester onward.
2. Concentrations of IGFs in the fetal circulation increase during pregnancy, and at term the concentrations of IGF-I are directly related to birth weight.
3. In mice, disruption of the *IGF* genes leads to severe growth retardation.
4. There is a striking increase in IGFBP-1 and IGFBP-2 concentrations in amniotic fluid at the end of the first trimester.
5. The major binding proteins in the human fetus are IGFBP-1 and IGFBP-2.

6. From as early as 16 weeks, there is an inverse correlation between fetal concentrations of IGFBP-1 and birth weight.
7. In the mother, circulating concentrations of IGF-I and IGFBP-1 increase during pregnancy.
8. Maternal IGFBP-1 concentrations are elevated in severe pre-eclampsia and IUGR.
9. Fetal concentrations of IGFBP-1 are elevated in cases of IUGR, especially those associated with specific evidence of reduced uteroplacental blood flow. Production of IGFBP-1 appears to be a sensitive indicator of the short- or long-term response to reduced fetal nutrition.

INSULIN

Although insulin is a major regulatory factor for carbohydrate metabolism, many lines of evidence demonstrate that it is a growth factor as well and has importance in fetal growth. Macrosomia is a well-known effect of fetal hyperinsulinism as is found in the infant of the diabetic mother. Increased weight gain in pregnant women over 40 lb leads to significantly increased risk of fetal macrosomia in gestational diabetes mellitus as well as in those with normal glucose tolerance test results. Errors in the normal pattern of *IGF-II* gene expression from the paternal chromosome and type 2 IGF receptor (for IGF-II) from the maternally derived gene underlie the pathogenesis of Beckwith-Wiedemann syndrome (OMIM #130650) a autosomal dominant disorder with mutation, deletion or hypermethylation of genes at 11p15.5. Affected infants are large and have elevated insulin concentrations; characteristics include exomphalos, macroglossia, and gigantism while hepatoblastoma and Wilms tumor may occur as as well.

Just as increased insulin stimulates fetal growth, syndromes of fetal insulin deficiency, such as congenital diabetes mellitus, pancreatic dysgenesis, or fetal insulin resistance (eg, leprechaunism), are characterized by IUGR. Infants born to diabetic mothers with vascular disease, hypertension, and/or eclampsia or pre-eclampsia also have IUGR and are born SGA. In that situation, it is clear that limited nutrient delivery compromises the growth of the infant.

EPIDERMAL GROWTH FACTOR

Epidermal growth factor (EGF) is involved with fetal growth, and expression varies with disordered fetal growth. Microvilli purified from the placentas of infants with IUGR have decreased or absent placental EGF receptor (EGF-R) phosphorylation and tyrosine kinase activity. Maternal smoking decreases birth weight by an average of 200 g, with the major effect occurring late in pregnancy; the placenta responds to smoking by significant changes in its vascularity, which leads to fetal hypoxia. There are decreased numbers of EGF-Rs and a reduced affinity of these receptors for EGF in the placentas of women who are smokers. Hypertensive patients also have decreased numbers of placental EGF-Rs, which may result in IUGR.

EGF levels in amniotic fluid are normally increased near term but decreased in pregnancies complicated by IUGR—although not, conversely, increased in infants who are large for gestational age.

EGF levels in the first urines to be voided by IUGR and macrosomic infants are lower than in control infants.

EGF administered to fetal monkeys results in histologic and biochemical maturation of their lungs, leading to improved air exchange and a diminished requirement for respiratory support. Surfactant apoprotein-A concentration and the lecithin-sphingomyelin ratio are both significantly higher in the amniotic fluid of EGF-treated fetuses. Whereas birth weight is not affected by EGF, adrenal and gastrointestinal (GI) system weights, standardized for body weight, are increased significantly. Furthermore, EGF stimulates GI muscle, GI enzyme maturation, and GI size improving the ability of the infant monkey to absorb nutrients. Lastly, EGF advances the maturation of the fetal adrenal cortex, increasing the expression of 3-beta-hydroxysteroid dehydrogenase.

FIBROBLAST GROWTH FACTOR

Genetically engineered fibroblast growth factor receptor 2 (FGF-R)-deficient mice are severely growth-retarded and die before gastrulation. Aberrant FGF signaling during limb and skeletal development in humans can lead to syndromes of dysmorphia. For example, achondroplasia (OMIM #100800) is due to mutations in the transmembrane domain of the type 3 FGF-R.

GENETIC, MATERNAL, AND UTERINE FACTORS

Maternal factors, often expressed through the uterine environment, exert more influence on birth size than paternal factors. The height of the mother correlates better with fetal size than the height of the father. However, there is a genetic component to length at birth that is not sex specific. Firstborn infants are on the average 100 g heavier than subsequent infants; maternal age over 38 years leads to decreased birth weight; and male infants are heavier than female infants by an average of 150 to 200 g. Poor maternal nutrition is the most important condition leading to low birth weight and length on a worldwide basis. Chronic maternal disease and eclampsia can also lead to poor fetal growth. Maternal alcohol ingestion has severe adverse effects on fetal length and mental development and predisposes to other physical abnormalities seen in the fetal alcohol syndrome; these include microcephaly, mental retardation, midfacial hypoplasia, short palpebral fissures, wide-bridged nose, long philtrum, and narrow vermilion border of the lips. Affected infants never recover from this loss of length but attain normal growth rates in the postnatal period. Abuse of other substances and chronic use of some medications (eg, phenytoin) can cause IUGR. Cigarette smoking causes not only retarded intrauterine growth but also decreased postnatal growth for as long as 5 years after parturition. Maternal infection—most commonly toxoplasmosis, rubella, cytomegalovirus infection, herpes simplex infection, and HIV infection—leads to many developmental abnormalities as well as short birth length. In multiple births, the weight of each fetus is usually less than that of the average singleton. Uterine tumors or malformations may decrease fetal growth.

CHROMOSOMAL ABNORMALITIES AND MALFORMATION SYNDROMES

Infants with abnormal karyotypes may have malformation syndromes and may also demonstrate poor fetal or postnatal growth. In most cases, endocrine abnormalities have not been noted. For further discussion of this extensive subject, the reader is referred to other sources listed in the references at the end of this chapter.

FETAL ORIGINS OF ADULT DISEASE

The metabolic syndrome consists of (1) hypertension, (2) impaired glucose tolerance, and (3) elevated triglycerides among other features (see Chapter 17). Insulin resistance is a cardinal feature and might be the basis for most or all of these complications or may be just one feature of the syndrome, according to some. The metabolic syndrome is one of the long-lasting effects of abnormalities in fetal growth. Evidence from many international studies indicates a relationship between low birth weight or low weight at 1 year of age and chronic disease in adulthood. An opposing view is that catch-up growth, rather than low birth weight, is responsible for these defects long into the child's future.

Inanition during the last two trimesters of pregnancy, which occurred during the famine in Holland during World War II, led to an 8% to 9% decrease in birth weight. On the other hand, in the Dutch famine, infants born after early gestational starvation of their mothers, but with improved maternal nutrition in late gestation were of normal size at birth. However, the female infants, born of normal size after this early gestational maternal starvation, themselves gave birth to small infants (SGA of 300-500 g decrease). In other populations, women with a history of SGA tend to have SGA infants themselves, and some studies show that generations of malnutrition must be followed by generations of normal nutrition before there is correction of the birth weight of subsequent infants. The sparse environment of the fetus early in gestation in a mother with various degrees of starvation *programs* the fetal metabolism for survival of the fetus but later in life these survival techniques become maladaptive in an environment of plenty. Insulin resistance in fetal life may spare nutrients from utilization in muscle, thus leaving them available for the brain; this mechanism would serve to minimize CNS damage in the fetus during periods of malnutrition. The complexity of the situation is not completely understood but is the target of extensive research *in vivo*, *in vitro*, and in long-term clinical studies.

Birth weight and rate of postnatal growth (ie, catch-up growth)—not prematurity alone—are inversely related to cardiovascular mortality and the prevalence of the metabolic syndrome. There is concern when a premature or SGA infant fails to gain weight after birth approximating the normal growth curve. Efforts are made to increase the growth rate often to the supramaximal velocity. Unfortunately, excessive growth soon after birth can also lead to obesity and its comorbidities later in life. It is not yet clear what the optimal nutrition is for a premature or SGA infant to avoid this metabolic programming. Further research as needed to determine the optimal growth rate for newborns experiencing poor intrauterine growth or premature delivery.

Studies of otherwise normal but thin children, who had a history of SGA, demonstrated insulin resistance before the teenage years, supporting the concept of early metabolic programming. Present-day adults, who were born in the Netherlands during the Dutch famine who had the lowest birth weights and the lowest maternal weights (those subjects whose mothers experienced malnutrition during the last two trimesters noted earlier), show a degree of insulin resistance that is directly related to their degree of SGA, further documenting the relationship between fetal undernutrition and adult insulin resistance as the etiology of poor growth.

On the other hand, macrosomic infants born to mothers with diabetes mellitus often develop childhood obesity and insulin resistance in later childhood even if they have a period of normal weight between 1 and 5 years of age. Remarkably, studies of the offspring of Dutch mothers exposed to famine during World War II in the first two trimesters (the time in which birth weight is least affected by maternal starvation) demonstrated a twofold increase in the incidence of obesity at 18 years of age, compared with a 40% decrease in the incidence of obesity if the individual was exposed to famine in the last trimester (the time in which birth weight is most negatively impacted by maternal starvation).

Individuals born SGA also have variations in pubertal development and reproductive hormones. SGA girls tend to have earlier puberty, or if puberty occurs at an average age, more rapid progression of puberty or polycystic ovarian syndrome (PCOS). Adult males born SGA have increased aromatase and increased 5-alpha reductase demonstrating effects on reproduction in the male as well as the female. In sum, prenatal and early postnatal growth affects the older child and adult in many ways.

POSTNATAL GROWTH

Postnatal growth in stature follows a characteristic pattern in normal children (Figures 6–1 and 6–2). The highest overall growth rate occurs in the fetus, the highest postnatal growth rate just after birth, and a slower growth rate follows in mid-childhood (Figures 6–3 and 6–4). There are two periods characterized by brief growth spurts in childhood: the infant-childhood growth spurt between 1½ years and 3 years and the mid-childhood growth spurt between 4 and 8 years. The mid-childhood growth spurt does not occur in all children, is more frequent in boys than girls, and its presence is hereditary. After another plateau, the striking increase in stature, the pubertal growth spurt follows, causing a second peak growth velocity. The final decrease in growth rate then ensues, until the epiphyses of the long bones fuse and growth ceases.

In addition, an *adiposity rebound* of accelerating weight gain and rising body mass index (BMI) occurs in early childhood after a period of relative stability of weight gain. An early adiposity rebound is a risk factor for the development of obesity later in childhood and thereafter.

Endocrine Factors

A. Growth hormone and insulin-like growth factors   As discussed in Chapter 4, somatotropin or GH is suppressed by hypothalamic GH release-inhibiting factor (somatostatin or SRIF) and stimulated by GH-releasing hormone (GHRH or GRF). The gene for GH is located on the long arm of chromosome 17 in a cluster of five genes: *GHN* codes for human GH (a single 191-amino-acid polypeptide chain with a molecular weight of 22 kD); *GHV* codes for a variant GH produced in the placenta; *CSH1* and *CSH2* codes for prolactin; and *CSHP1* codes for a variant prolactin molecule. A 20-kD variant of pituitary GH accounts for 5% to 10% of circulating GH and is derived from the same gene as the 22K variant, *GHN*, but results from alternative splicing. The 20-kD variant is poorly characterized but when derived from the

placental gene, *GHV*, *in vitro* it has less diabetogenic effect but similar growth-promoting and lipolytic activity.

The effects of GH are mainly mediated by the IGFs, but GH also directly stimulates lipolysis, increased amino acid transport into tissues, and increased protein and glucose synthesis in liver. It also has direct effect on cartilage growth. GH in excess causes insulin resistance and is diabetogenic. GH is secreted in a pulsatile manner, so that serum concentrations are low much of the day, but peak during short intervals. Values are higher in the immediate neonatal period, decrease through childhood, and rise again as a result of increased pulse amplitude (but not frequency) during puberty. GH secretion falls again during aging.

GH circulates in plasma bound to a protein, the GH-binding protein (GHBP), with a sequence equivalent to that of the
FIGURE 6–2 Growth chart for girls in most clinical situations showing the 3rd to 97th percentiles. The lines for the 3rd and the 97th percentiles approximate those for −2.5 SDs and +2.5 SDs from the mean. (Reproduced with permission from National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion. http://www.cdc.gov/growthcharts. Published May 30, 2000.)

extracellular membrane domain of the GH receptor from which it is cleaved. The physiology of the GHBP appears to reflect important interrelationships between GH and GHR in terms of effects on growth. For example, obese patients have lower plasma GH concentrations but higher GHBP levels, whereas starvation raises GH concentrations and lowers GHBP levels. Patients with abnormalities of the GH receptor (eg, Laron dwarfism) also have a defect reflected in the serum GHBP concentrations; those with decreased numbers of GH receptors have decreased serum GHBP concentrations. Patients who are unable to dimerize the GH receptors to allow activation of the GH-GHR complex or those who have intracellular defects in the JAK-STAT system have no alteration in GHBP concentration, but are short (see Chapters 1 and 4).

GH exerts its effects on growth mainly, but not solely, through the IGFs and their binding proteins. IGF-I and IGF-II have

structures similar to that of the proinsulin molecule but differ from insulin in regulation, receptors, and biologic effects. The IGFs were originally called sulfation factor and then somatomedin. The single copy gene for pre-pro-IGF-I is located on the long arm of chromosome 12. Post-translational processing produces the 70-amino acid mature form; alternative splicing mechanisms produce structural variants of the molecule. The IGF-I cell membrane receptor (the type 1 receptor) resembles the insulin receptor in its structure consisting of two alpha and two beta chains. Binding of IGF-I to type 1 receptors stimulates tyrosine kinase activity and autophosphorylation of tyrosine residues in the receptor. This leads to cell differentiation or division (or both). IGF-I receptors are downregulated by increased IGF-I concentrations, whereas decreased IGF-I concentrations increase IGF-I receptors.

IGF molecules in the circulation are mostly bound to one of eight IGFBPs. IGFBP-1 and IGFBP-3 have been most extensively
FIGURE 6–3 Reference curves for height velocity for boys aged 6 to 19 years according to onset of puberty. The median and the 3rd and 97th percentiles for earlier onset puberty is in blue, for average onset is in black, and for later onset is in red. Earlier puberty was defined as age of onset 10.2 years, average onset as occurring between 10.2 and 11.8 years, and later puberty as onset at age >11.8 years. The charts can be used clinically by calculating the yearly increment in stature as the difference between measurements of height at 2 times $(g_2 - g_1)$ divided by the difference of the age of the child at the first measurement subtracted from the age at the second measurement, $(t_2 - t_1)$. The quotient of this division is plotted on the chart as a bar which starts at the initial age of the child and ends at the age of the child at the end of the interval with the center of the bar plotted at the age $(t_1 + t_2)/2$. (Reproduced with permission from Kelly A, Winer KK, Kalkwarf H. Age-based reference ranges for annual height velocity in US children. *J Clin Endocrinol Metab*. 2014 Jun;99(6):2104-2112.)

FIGURE 6–4 Reference curves for height velocity for girls aged 6 to 17 years according to onset of puberty. The median and the 3rd and 97th percentiles for earlier onset puberty is in blue, for average onset is in black, and for later onset is in red. Earlier puberty was defined as age of onset 10.2 years, average onset as occurring between 10.2 and 11.8 years, and later puberty as onset at age >11.8 years. The charts can be used clinically by calculating the yearly increment in stature as the difference between measurements of height at 2 times $(g_2 - g_1)$ divided by the difference of the age of the child at the first measurement subtracted from the age at the second measurement $(t_2 - t_1)$. The quotient of this division is plotted on the chart as a bar which starts at the initial age of the child and ends at the age of the child at the end of the interval with the center of the bar plotted at the age $(t_1 + t_2)/2$. studied. IGFBP-1 is a 25-kD protein and mainly inhibits IGF-I action. Serum levels of IGFBP-1 are inversely proportional to insulin levels. This protein does not appear to be regulated by GH. It is present in high concentrations in fetal serum and amniotic fluid. Newborn serum concentrations of IGFBP-1 are inversely proportional to birth weight.

IGF-I circulates bound to IGFBP-3 and an acid labile subunit (ALS) in a 150-kD complex. Abnormalities of the ALS lead to decreased growth. Serum IGFBP-3 concentrations are directly proportional to GH concentrations but also to nutritional status. In malnutrition, IGFBP-3 and IGF-I levels fall, while GH rises as does IGFBP-1. IGF-I directly regulates IGFBP-3 as well. IGFBP-3 rises with advancing age through childhood, with highest values achieved during puberty; however, the pattern of change of IGF-I at puberty is different from that of IGFBP-3. The molar ratio of IGF-I to IGFBP-3 rises at puberty, suggesting that more IGF-I is free to influence growth during this period.

IGF-I is produced in most tissues and is exported to neighboring cells to act on them in a paracrine manner or on the cell of origin in an autocrine manner. Thus, serum IGF-I concentrations may not reflect the most significant actions of this growth factor. The liver is a major site of IGF-I synthesis, and much of the circulating IGF-I probably originates in the liver; serum IGF-I concentrations vary in liver disease, falling with reductions in functional hepatic mass. IGF-I is a progression factor, so that a cell which has been exposed to a competence factor such as platelet-derived growth factor (PDGF) in stage G_0 of the cell cycle and has progressed to G_1 can, with IGF-I exposure in G_1, undergo division in the S phase of the cell cycle. Aside from the stimulatory effects of IGF-I on cartilage growth, IGF-I has stimulatory effects on hematopoiesis, ovarian steroidogenesis, myoblast proliferation and differentiation, and differentiation of the lens.

IGF-I is now available in recombinant form. IGF-I administration increases nitrogen retention and decreases blood urea nitrogen. While GH is diabetogenic, IGF-I can lower blood sugar values. In GH-resistant patients (Laron dwarfs), IGF-I stimulates growth in the absence of GH. IGF-I is approved by the Food and Drug Administration (FDA) for use in short stature due to primary IGF-I deficiency. IGF-II is a 67-amino acid peptide. The gene for pre-pro-IGF-II is located on the short arm of chromosome 11, close to the gene for preproinsulin. The type 2 IGF receptor (cation-independent mannose 6-phosphate receptor) preferentially binds IGF-II and is identical to the mannose 6-phosphate receptor, a single-chain transmembrane protein. Although most of the effects of IGF-II appear to be mediated by its interaction with the type 1 receptor, independent actions of IGF-II, via the type 2 receptor, have been described.

Plasma concentrations of the IGFs vary with age and physiologic condition. IGF-I concentrations are low at term in neonates and remain relatively low in childhood until a peak is reached during puberty, with values rising higher than at any other time in life. Serum IGF-I then decreases to adult levels, values higher than in childhood but lower than in puberty. With advancing age, serum GH and IGF-I levels decrease. IGF-I concentrations are more highly correlated in monozygotic twins than in same-sex dizygotic twins, indicating a genetic effect on regulation of IGF-I levels.

GH deficiency leads to lower serum IGF-I and IGF-II concentrations, whereas GH excess leads to elevated IGF-I but no rise in IGF-II above normal. Because serum IGF-I is lower during states of nutritional deficiency, IGF-I is not a perfect tool in the differential diagnosis of conditions of poor growth, which often include impaired nutritional state. IGF-I suppresses GH secretion by a negative feedback mechanism, so that patients who lack GH receptors (Laron dwarfs) or who are unable to produce IGF-I, have elevated GH concentrations but negligible IGF-I concentrations. Rare patients with poor growth who lack IGF-I receptors have elevated concentrations of IGF-I which exerts no biological activity.

B. Thyroid hormone   As noted earlier, newborns with congenital hypothyroidism are of normal length, but if untreated, they manifest exceedingly poor growth soon after birth. Infants with untreated congenital hypothyroidism suffer permanent developmental delay so early treatment is necessary. Newborn screening for congenital hypothyroidism is universal in the United States and most countries. Acquired hypothyroidism with onset after 3 years leads to a markedly decreased growth rate but no permanent intellectual defects. Bone age advancement is severely delayed in hypothyroidism, usually more so than in GH deficiency, and epiphyseal dysgenesis is seen as calcification of the epiphyses progresses. The normal decrease in the upper to lower segment ratio (U/L ratio) with age (Figure 6–5) is delayed, and therefore, the U/L ratio is elevated, owing to poor lower limb growth in hypothyroidism.

C. Sex steroids   Gonadal sex steroids exert an important influence on the pubertal growth spurt, whereas absence of these
FIGURE 6–5 Normal upper:lower segment (US:LS) ratios, based on findings in 1015 white children. Values are slightly lower for black children. (Reproduced with permission from McKusick V. *Hereditable Disorders of Connective Tissue.* 4th ed. St. Louis: Mosby; 1972.)

factors is not of major importance in prepubertal growth. Gonadal and adrenal sex steroids in excess can cause a sharp increase in growth rate as well as the premature appearance and progression of secondary sexual features. If unabated, increased sex steroids will cause advancement of skeletal age, premature epiphyseal fusion, and short adult stature all mediated by estrogen. The pubertal rise in gonadal steroids exerts direct and indirect effects on IGF-I production. Estradiol (secreted or aromatized from testosterone) directly stimulates the production of IGF-I from cartilage and also increases GH secretion, which stimulates IGF-I production indirectly. Both actions appear important in the pubertal growth spurt.

D. Glucocorticoids   Endogenous or exogenous glucocorticoids in excess quickly decrease growth rate; this effect occurs more quickly than weight gain. The absence of glucocorticoids has little effect on growth if the individual is clinically well in other respects (eg, in the absence of hypotension or hypoglycemia).

Other Factors

A. Genetic factors   Genetic factors influence adult height. There is correlation between midparental height and the child's height; appropriate methods to utilize this phenomenon and determine the target height for a child are presented in Figure 6–6.
FIGURE 6–6 Determination of target height in a shorter family. This 10-year-old boy is 124 cm tall, his mother is 61 inches tall (adults recall their heights in inches and feet but, if they are available, their height should be actually measured in centimeters), and the father is 63 inches tall. Five inches are added to the mother's height to convert her height percentile to the equivalent percentile on a boy's chart. (If we were considering a daughter whose height is plotted on a girl's chart, the mother's height would be directly plotted and 5 inches would be subtracted from the father's height to correct his height percentile to the equivalent for an adult woman.) Her corrected height and that of the father are plotted at the far right of the chart where adult heights are displayed. The corrected midparental height is calculated by adding the father's height to the corrected mother's height, and the sum is divided by two; the result is called the target height. The limits of 2 SDs above and below the target height are displayed by plotting 2 SDs (~4 inches above and below the target height). This process is equivalent to moving the 50th percentile for the U.S. population to a conceptual 50th percentile for the family under consideration. It is evident that the height of the child, although below the 3rd percentile for the United States, is within the bounds of the percentiles described by ±2 SD from the target height, and the child appears to fit within the genetic pattern of the family. The growth velocity and the degree of skeletal maturation are some of the factors necessary to evaluate this child in more detail.

B. Socioeconomic factors Worldwide, the most common cause of short stature is poverty and its effects. Thus, poor nutrition, poor hygiene, and poor health influence growth both before and after birth. Parasitic infection is prevalent in less developed countries and severely stunts growth and depletes energy. In people of the same ethnic group and in the same geographic location, variations in stature are often attributable to socioeconomic factors. For example, Japanese individuals born and reared in North America after World War II were generally taller than Japanese-born immigrants moving to North America. Conversely, when other factors are equal, the differences in average height between various ethnic groups are mainly genetic. The newest growth charts for children in the United States published by the Centers for Disease Control and Prevention (CDC) in 2001 are not ethnicity-specific because it is believed that the major growth differences between ethnic groups are due to socioeconomic status and nutrition rather than genetic endowments. Indeed, the World Health Organization (WHO) has developed internationally relevant growth charts for all populations. The data for the construction of these charts is derived from well-nourished breastfed infants.

C. Nutritional factors The influence of malnutrition accounts for much of the socioeconomic discrepancy in height noted earlier, but malnutrition may occur in the midst of plenty and must always be suspected in disorders of growth. Other factors may be blamed for poor growth when nutritional deficiencies are actually responsible. For example, Sherpas were thought to have short stature mainly because of genetic factors or the effects of high altitude living on the slopes of Mount Everest; however, nutritional supplementation increased stature in this group, demonstrating the effects of adequate nutrition. The developed world places a premium on appearance, and women portrayed as beautiful in the media are characteristically thin. Significant numbers of children, chiefly teenagers, voluntarily decrease their caloric intake even if they are not obese; this accounts for some cases of poor growth. Chronic disease, which hampers adequate nutrition, often leads to short stature. For example, bronchopulmonary dysplasia decreases growth to some degree because it increases metabolic demands, shifting nutrient usage away from growth; improved nutrition increases growth in these patients. Celiac disease is another common gastrointestinal disorder that impairs growth, pubertal development, menstruation, and bone acquisition.

Feeding problems in infants, resulting from inexperience of parents or poor child–parent interactions (so-called maternal deprivation), may account for poor growth. Fad diets, such as poorly constructed vegan diets that put children at risk for vitamin B_{12} or iron deficiency, as well as major dietary manipulation, such as a severely low-fat diet, may place children at risk for deficiency of fat-soluble vitamins. Deliberate starvation of children by caregivers is an extreme form of child abuse that may be first discovered because of poor growth.

Remarkably, obesity increases IGF-I concentrations by increasing GH receptors even though GH secretion is suppressed to levels that might suggest GH deficiency, thereby complicating the diagnosis of true GH deficiency in the obese. There are significant endocrine changes associated with malnutrition. Decreased GH receptors or post-receptor defects in GH action, leading to decreased production of IGF-I and decreased concentration of serum IGF-I, are notable. The characteristic results of malnutrition are an elevation of serum GH, and a decrease in IGF-I. IGFBP-1, a suppressor of IGF-I effects, is elevated in malnutrition.

D. Psychologic factors Aberrant intrafamilial dynamics, psychologic stress, or psychiatric disease can inhibit growth either by altering endocrine function or by secondary effects on nutrition (psychosocial dwarfism or maternal deprivation). It is essential to diagnose those situations that might suggest organic disease states, as the management approach is very different in malnutrition.

E. Chronic disease Many chronic systemic diseases interfere with growth independent of poor nutrition. For example, congestive heart failure and asthma, if uncontrolled, are associated with decreased stature; in some cases, adult height is in the normal range because growth continues over a longer period of time. Children of mothers with HIV infection are often small at birth and have an increased incidence of poor postnatal growth, delayed bone age development, and reduced IGF-I concentrations. In addition, thyroid dysfunction may develop, further complicating the growth pattern. Infants born of HIV-infected mothers, who are not infected themselves, may exhibit catch-up growth.

Catch-up Growth

Correction of growth-retarding disorders may be temporarily followed by an abnormally high-growth rate as the child approaches normal height for age. This catch-up growth occurs after initiation of therapy for hypothyroidism and GH deficiency, after correction of glucocorticoid excess, and after appropriate treatment of many chronic diseases such as celiac disease. Catch-up growth is usually short-lived and is followed by a more typical growth rate. Catch-up growth after an SGA birth may not be beneficial as it is linked to metabolic disease, hypertension, obesity, and comorbid illnesses related to insulin resistance, by the age of 30 years.

MEASUREMENT OF GROWTH

Accurate measurement of height is an essential part of the physical examination of children and adolescents. The onset of a chronic disease may often be determined by an inflection point in the growth chart. In other cases, a detailed growth chart indicates a normal constant growth rate in a child observed to be short for age. If careful growth records are kept, a diagnosis of constitutional delay in growth and adolescence or genetic short stature may be made in such a patient; without previous measurements, the child might be subjected to unnecessary diagnostic testing, or months of delay may occur as the child's growth is finally carefully monitored. Poor measurement technique may suggest lack of

growth in a child who is growing normally, subjecting the child to unnecessary testing as well.

Height

The National Center for Health Statistics (NCHS) revised the growth charts for children in the United States in 2000 (see Figures 6–1 and 6–2). These charts display the 3rd and 97th percentiles rather than the 5th and 95th percentiles, and SDs of height for age are also available. Charts displaying BMI by age contain data appropriate for the evaluation of obesity and underweight. All of these charts are available online from the CDC.

The limits of the CDC growth charts showing the 3rd and the 97th percentile still leave 6 of 100 healthy children outside of their boundaries, with 3 of 100 below the more worrisome (to parents) *lower limits of normal*. It is both unnecessary and impractical to evaluate 3% of the population. Instead, the examining physician should determine which short children warrant further evaluation and which ones (and their parents) require only reassurance that they are healthy. When parents see that their child is below the 3rd percentile and in a section of the chart colored differently from the *normal area*, they assume that there is a serious problem. Thus, the format of the chart can dictate parental reaction to height, because all parents want their children to be in the *normal range*. Figures 6–1 and 6–2 furnish data necessary to evaluate the height of children at various ages using percentiles or the SD method used by the WHO. SD determination is more useful in extremely short children below the second or 1st percentile. CDC Z score data, equivalent to heights down to 2 SD below the mean for stature by age and gender is found at http://www.cdc.gov/growthcharts/zscore.htm.

Pathologic short stature is defined by different authorities in different manners. The Pediatric Endocrine Society (PES) uses less than 2 SD below the mean for age and gender or the 2.3 percentile, and the FDA uses –2.25 SDs or the 1.22 percentile for consideration of GH therapy for ISS. Since the CDC charts denote the 3% at the lowest line on the chart, one might approximate this to the (PES) definition of short stature. However, a diagnosis of pathologic short stature should not be based on a single measurement. Serial measurements are required because they allow determination of growth velocity, which is a more sensitive index of the growth process than a single determination. A very tall child who develops a postnatal growth problem will not fall below the 3rd percentile for years but will fall below the mean in growth velocity soon after the onset of the disorder. As Figures 6–3 and 6–4 demonstrate, growth velocity varies at different ages, but as a rough guide, a growth rate of less than 5 cm/y between age 4 years and the onset of puberty is abnormal. In children under 4 years of age, normal growth velocity changes more strikingly with age. A growth rate less than two SD below mean for age or height, corrected for midparental height, of less than –2 SD is worthy of attention. The Growth Hormone Research Society adds other criteria of concern: signs indicative of an intracranial lesion, signs of multiple pituitary hormone deficiencies, symptoms and signs of GH deficiency in the newborn and a history of CNS radiation. The more of the criteria met, the more likely is a disorder of growth.

Growth charts for premature infants ("Fenton growth curves") are available at http://pedinfo.org/growth.php. Growth charts for special populations are also available at that website; thus growth charts for achondroplasia, Down syndrome, Noonan syndrome, Williams syndrome, Turner syndrome, Russell-Silver syndrome, and other conditions can also be found.

Healthy term newborns tend to be clustered in length measurements around 21 inches (often owing to mistakes in obtaining accurate measurements). In the ensuing 24 postnatal months, the healthy child's height will enter a channel on the growth chart and remain there throughout childhood. Thus, a child with constitutional delay in growth or genetic short stature, whose height is at the mean at birth and gradually falls to the 10th percentile at 1 year of age and to the 5th percentile by 2 years of age, may in fact be healthy in spite of crossing percentile lines in the journey to a growth channel at the 5th percentile. Although the growth rate may decrease during these years, it should not be less than the 5th percentile for age. A steeper decrease in growth rate may be a sign of disease. Alternatively, catch-up growth after SGA birth will send the child to a higher height percentile. As stated earlier, catch-up growth from SGA is linked by some evidence to metabolic disease, particularly insulin resistance later in life. When a question of abnormal growth arises, previous measurements are essential. Every physician treating children should record supine length (<2 years of age) or standing height (>2 years of age) as well as weight at every office visit. As the child leaves infancy, height and growth velocity should be determined in relation to the standards for the child's age on a graphic chart with indication of the child's position (supine or standing) at measurement, which is especially important at the time children switch from lying to standing at about 2 years of age. Failure to recognize a change in measurement technique as the child moves from lying to standing may falsely suggest a growth problem.

Patients who cannot be measured in the standing position (eg, because of cerebral palsy) require other approaches. The use of arm span is a possible surrogate for the measurement of height, and there are formulas available for the calculation of height based on the measurement of upper arm length, tibial length, and knee length (see later).

This discussion presupposes accuracy of measurements. However, it is reported that screening examinations in the real world fall short of that ideal. Forty-one percent of a presumably normal population screened at a school in England met the criteria for evaluation of abnormal growth (approximately two-thirds grew faster than the normal growth category and one-third were in the slower than normal category), leading to an unreasonable size of a referral population, all due to simple measuring errors.

Relation to Midparental Height: The Target Height

There is a positive correlation between midparental height (the average of the heights of both parents) and the stature of a child. One way to use this relationship of parents' heights to the expected heights of children within a given family is to calculate target adult height range using parents' heights, correcting these

heights for the sex of the child and plotting the results on the child's growth chart. There is an average 5-inch height difference between adult men and women in the United States. Thus, for boys, add 5 inches to the mother's height, add the result to the father's height, and divide by two. This is the target height, and it is expected that sons of these parents will reach a height within two SD of this target—or, for simplicity, within 4 inches above or 4 inches below the target height (2 inches approximates one SD for adult stature). For girls, subtract 5 inches from the father's height and add the result to the mother's height and divide by two, leading to the target height for the girl. The range for girls will also be within 4 inches above and below this target. In effect, this corrects the North American growth charts for the particular family being considered. The calculated target height corresponds to the 50th percentile for the family, and the limits of the ±2 SD approximate the 5th to 95th percentile for the family. This method is useful only in the absence of disease affecting growth, and the prediction is more valid when the parents are of similar rather than of widely different heights. Figures 6–6 and 6–7 demonstrate the calculation of target height and the ranges. When there is a large discrepancy between the heights of the mother and the father, prediction of target height becomes difficult. A child may follow the growth pattern of the shorter parent more closely than the midparental height. A boy may, for example, follow the growth pattern of a short mother rather than a taller father.

A parent who spent the growing years in poverty, with chronic disease, or in an area of political unrest might have shorter adult height, due to nutritional factors or disease, that may not be passed on to the children. Of course, the height of an adopted child will have no relationship to the adoptive parents' heights. All of these factors must be determined by history.

Technique of Measurement

Length and height must be measured accurately. Hasty measurements derived from marks made on paper at an infant's foot and head while the infant is squirming on the paper on the examining table are useless. Infants must be measured on a firm horizontal surface with a permanently attached rule, a stationary plate perpendicular to the rule for the head, and a movable perpendicular plate for the feet. One person should hold the head stable while another makes sure the knees are straight and the feet are firm against the movable plate. There are calipers-like devices (eg, infantometer) that can be used for such accurate measurements.

Children over age two are measured standing up. Standing height is on the average 1.25 cm less than supine length, and it is essential to record the position of measurement each time during the change over from lying to standing height at 2 to 3 years of age; shifting from supine height at 2 years to standing height at 2½ years can falsely suggest an inadequate growth rate over that 6-month period.

Standing measurements cannot be accurately performed with the measuring rod that projects above the common weight scale; the rod is too flexible, and the scale footplate will in fact drop lower when the patient stands on it. Instead, height should be measured with the child standing back to the wall with heels at the wall, ankles together, and knees and spine straight against a vertical metal rule permanently attached to the wall or to a wide upright board. The child's head is to be horizontal with the eyes looking ahead and the chin gently elevated if necessary (Frankfort plane). Height is measured at the top of the head by a sliding perpendicular plate (or square wooden block). A Harpenden stadiometer is a mechanical measuring device capable of such accurate measurement. It is preferable to measure in the metric system, because the smaller gradations make measurements more accurate by minimizing the effect of rounding off numbers.

Growth is not constant but is characterized by short spurts and periods of slowed growth. The interval between growth measurements should be adequate to allow an accurate evaluation of growth velocity. Appropriate sampling intervals vary with age but should not be less than 3 months in childhood, with a 6-month interval being optimal.

The problem of measuring the growth rate of children with orthopedic deformities or contractures is significant, because these patients may have nutritional and/or endocrine disorders as well. The measurement of knee height, tibial length, or upper arm length correlates well with standing height ($r = 0.97$); thus, these measurements may be translated, using special linear regression equations, into total height, which is then plotted on standard growth charts. Specialized laser-calibrated devices to measure tibial length (kneeometry) are reported to be accurate for assessment of short-term growth down to weekly intervals.

In addition to height or length, other significant measurements include: (1) the frontal-occipital head circumference; (2) horizontal arm span (between the outspread middle fingertips with the patient standing against a flat backboard); and (3) the upper segment (US) to lower segment (LS) ratio. For the latter, the LS is measured from the top of the symphysis pubis vertically to the floor with the patient standing straight, and the US is determined by subtracting the LS from the accurate standing height measurement noted earlier. (Normal standard US-LS ratios are shown in Figure 6–5.) These measurements become important in skeletal or reproductive disorders. Sitting height is used in some clinical studies of growth, but the sitting stadiometer is rarely available.

Height and Growth Rate Summary

In summary, we consider three criteria for pathologic short stature: (1) height more than 2–2.25 SD below the mean for chronologic age; (2) growth rate more than 2 SD below the mean for chronologic age; and (3) height more than 2 SD below the target height when corrected for midparental height.

Weight and BMI

The measured weight should be plotted for age on standard graphs developed by the NCHS. These are available online (http://www.cdc.gov/growthcharts/clinical_charts.htm). BMI charts displaying percentiles of BMI (weight in kilograms divided by height in meters squared) are widely available and provide an essential method to assess nutritional status.
FIGURE 6–7 Determination of target height in a taller family. This 10-year-old boy is 124 cm tall just as in Figure 6–6, his mother is 65 inches tall, and the father is 73.5 inches tall. Five inches are added to the mother's height to convert her height percentile to the equivalent percentile on a boy's chart. (If we were considering a daughter whose height is plotted on a girl's chart, the mother's height would be directly plotted and 5 inches would be subtracted from the father's height to correct his height percentile to the equivalent height percentile for an adult woman.) Her corrected height and that of the father are plotted at the far right of the chart where adult heights are displayed. The corrected midparental height is calculated by adding the father's height to the corrected mother's height, and the sum is divided by 2; the result is the target height. The limits of 2 SDs above and below the target heights are displayed by plotting 2 SDs (about 4 inches above and below the target height). This is equivalent to moving the 50th percentile for the United States population to a conceptual 50th percentile for the family under consideration. It is evident that the height of the child, which is below the 3rd percentile for the United States, is even farther outside the bounds of the percentiles described by ±2 SD from the target height, and, thus, the child appears to fall far outside the genetic pattern of the family, and this is of clinical concern. The growth velocity and the degree of skeletal maturation are some of the other factors necessary to evaluate this child's growth in more detail.

SKELETAL (BONE) AGE

Skeletal development is a general reflection of physiologic maturation but there is significant variation. For example, menarche is better correlated with a bone age of 13 years than with a given chronologic age. However, bone age is as variable as chronologic age at the onset of puberty.

Estrogen plays the major role in advancing skeletal maturation. Patients with aromatase deficiency, who cannot convert testosterone to estradiol, and patients with estrogen receptor defects, who cannot respond to estrogen, grow taller well into their twenties without having epiphysial fusion. Bone age indicates remaining growth available to a child and can be used to predict adult height. However, bone age is not a definitive diagnostic test of any disease; it can assist in diagnosis only when considered along with other factors.

Bone age is determined by comparing the shapes and stage of fusion of epiphyses or bones on the patient's radiograph with an atlas demonstrating normal skeletal maturation for various ages. The Greulich and Pyle Atlas of radiographs of the left hand and wrist is most commonly used in the United States, but other methods of skeletal age determination, such as Tanner and Whitehouse maturity scoring, are preferred in Europe. Any bone age more than two SD above or below the mean for chronologic age is out of the normal range. The SD of bone age readings for chronological age is a full year by the mid teenage years, indicating the imprecision of prediction; thus at a chronological age of 15 years, the bone age can normally range from 13 to 17. Further, there appear to be ethnic differences in bone age maturation that is not reflected in the guidelines for interpretation. For newborn infants, knee and foot radiographs are compared with an appropriate bone age atlas. For late pubertal children, just before epiphyseal fusion, the knee atlas reveals whether any further growth can be expected or whether the epiphyses are fused. All the methods are imperfect, as there is great variation in bone age in relation to chronologic age even in typically developing children.

Height prediction in the United States utilizes the bone age reading and height measurement at the time the radiograph was taken and the Bayley-Pinneau tables in the Greulich and Pyle Skeletal Atlas of the hand to determine the amount of growth left before epiphyseal fusion. A chart to predict adult height of a typically developing child without the use of bone age is found in the Cole reference below. Height prediction by any method becomes more accurate as the child approaches the time of epiphyseal fusion.

DISORDERS OF GROWTH

SHORT STATURE DUE TO NONENDOCRINE CAUSES

There are many causes of decreased childhood growth and short adult height (Table 6–1). The following discussion covers only the more common conditions, emphasizing those that might be

TABLE 6–1 Causes of abnormalities of growth.

I. CAUSES OF SHORT STATURE

Nonendocrine Causes	Endocrine Disorders
Constitutional short stature	GH deficiency and variants
Genetic short stature	Congenital GH deficiency
Intrauterine growth retardation and SGA	Isolated GH deficiency
Syndromes of short stature	With other pituitary hormone deficiencies
Turner syndrome and its variants	With midline defects
Noonan syndrome	Pituitary agenesis
Bardet-Biedl syndromes	Holoprosencephaly
Other autosomal abnormalities and dysmorphic syndromes	Other anomalies
Chronic disease	Acquired GH deficiency
Cardiac disorders	Hypothalamic-pituitary tumors
Left to right shunt	Histiocytosis X
Congestive heart failure	Central nervous system infections
Pulmonary disorders	Head injuries
Cystic fibrosis	GH deficiency following cranial irradiation
Asthma	Central nervous system vascular accidents
Gastrointestinal disorders	Hydrocephalus
Malabsorption	Empty sella syndrome
Celiac disease	Abnormalities of GH action
Disorders of swallowing	Primary IGF-I deficiency
Hepatic disorders	Laron dwarfism
Hematologic disorders	Pygmies
Sickle cell anemia	IGF-I receptor defect
Thalassemia	Psychosocial dwarfism
Renal disorders	Hypothyroidism
Renal tubular acidosis	Glucocorticoid excess (Cushing syndrome)
Chronic uremia	Endogenous
Immunologic disorders	Exogenous
Connective tissue disease	Psuedohypoparathyroidism/ Albrights Hereditary Osteodystrophy
Juvenile rheumatoid arthritis	Disorders of vitamin D metabolism
Chronic infection	Diabetes mellitus, poorly controlled
Central nervous system disorders	
Malnutrition	
Decreased bioavailability of nutrients	
Fad diets	
Voluntary dieting	
Anorexia nervosa	
Anorexia of cancer chemotherapy	
Parasites	

II. CAUSES OF TALL STATURE

Nonendocrine Causes	Endocrine Disorders
Constitutional tall stature	Pituitary gigantism
Genetic tall stature	Sexual precocity
Syndromes of tall stature	Thyrotoxicosis
Cerebral gigantism	Infants of diabetic mothers
Marfan syndrome	
Homocystinuria	
Beckwith-Wiedemann syndrome	
XYY and XYYY syndromes	
Klinefelter syndrome	

included in an endocrine differential diagnosis. Shorter than average stature need not be considered a disease, because variation in stature is a normal feature of human beings, and a normal child should not be burdened with a misdiagnosis. Although the classifications described later may apply to most patients, some will still be resistant to definitive diagnosis.

1. CONSTITUTIONAL SHORT STATURE

Constitutional short stature (constitutional delay in growth and adolescence) is not a disease but rather a variation from normal for the population and is considered a slowing of the pace of development. There is usually an associated delay in pubertal development as well as a decrease in growth (see Constitutional Delay in Adolescence, Chapter 15). It is characterized by moderate short stature (usually not far below the 3rd percentile), thin habitus, and retardation of bone age. The family history often includes similarly affected members (eg, mother with delayed menarche or father who first shaved later than peers and continued to grow past his teen years).

All other causes of decreased growth must be considered and ruled out before this diagnosis can be made with confidence. The patient may be considered physiologically (but not mentally) delayed in development. Characteristic growth patterns include normal birth length and height, with a gradual decrease in percentiles of height for age by 2 years; in contrast, a rapid decrease in percentiles is an ominous sign of pathology. Onset of puberty is usually delayed for chronologic age but normal for skeletal age. Adult height is in the normal range but varies according to parental heights. Adult height is often less than the predicted height, because growth is less than expected during puberty. Aromatase inhibitors have been used in clinical studies for boys with constitutional delay in growth to inhibit the conversion of androgens to estrogen so that bone age does not advance and growth continues longer. While this is still an experimental treatment, most studies suggest that it causes no ill effects, although long-term data dealing with effects on bone mineral density as a result of the use of these agents are not available. Elevated testosterone levels and testicular enlargement result from aromatase inhibition.

2. FAMILIAL SHORT STATURE

Short stature may also occur in a familial pattern without retarded bone age or delay in puberty; this is considered **familial short stature**. Affected children are closer to the mean on the normal population growth charts after familial correction for mid-parental height by calculation of the target height (see Figures 6–6 and 6–7). Adult height depends on the mother's and father's heights. Patients with the combination of constitutional short stature and genetic short stature are quite noticeably short due to both factors, and these patients are most likely to seek evaluation. Boys are brought to consultation more often than girls. Children in these families may be born AGA but exhibit slowed growth in the first two postnatal years; this process is gradual in comparison to the striking changes in growth rate that are characteristic of diseases that primarily affect growth, but it may still be difficult to tell the difference without extended observation.

3. PREMATURITY AND SGA

Although the majority of SGA infants show catch-up growth, about 20% may follow a lifelong pattern of short stature. In comparison, AGA premature infants usually catch up to the normal range of height and weight by 1 to 2 years of age. Severely premature infants with birth weights less than 800 g (that are AGA), however, may maintain their growth retardation at least through their third year; only follow-up studies will determine whether this group of premature infants reaches reduced adult heights. Bone age and yearly growth rate are normal in SGA patients until puberty occurs, and the patients are characteristically thin. However, SGA is a risk factor for premature thelarche or early menarche, although catch up growth after SGA may be responsible for this tendency, so bone age may advance more rapidly in this subset of SGA (see Chapter 15).

Within this grouping are many distinctive genetic or sporadically occurring syndromes. The most common example is Russell-Silver dwarfism (OMIM #180860), characterized by small size at birth, triangular facies, and a variable degree of asymmetry of the extremities; this condition is due to epigenetic changes of DNA hypomethylation at the telomeric imprinting control region (ICR1) on chromosome 11p15, involving the *H19* and *IGF-II* genes or to maternal, uniparental disomy of chromosome 7. Intrauterine infections with *Toxoplasma gondii*, rubella virus, cytomegalovirus, herpesvirus, and HIV are noted to cause SGA. Furthermore, maternal drug usage, either illicit (eg, cocaine), legal but ill-advised (eg, alcohol during pregnancy), or legally prescribed medication (eg, phenytoin) may cause SGA. Reports of other syndromes in SGA infants can be found in sources listed in the bibliography.

Although SGA is not an endocrine cause of short stature, GH treatment is approved by the FDA and leads to increased adult height. Those SGA infants with the Δ3-isoform (genomic deletion of exon 3) of the GH receptor (GHR) are more likely to catch up on GH therapy, as are girls with Turner syndrome, although this benefit is transient and some data refute this differential response to treatment.

There are many endocrine sequelae with SGA birth including premature adrenarche, puberty, and menarche in girls and dyslipidemia and insulin resistance in boys and girls. Girls have a predilection to develop PCOS after being SGA. GH antagonizes the action of insulin and given the tendency for SGA children to have insulin resistance, there may be concerns regarding the potential additive effects. Recent studies of insulin sensitivity in SGA subjects receiving GH treatment indicate that in most cases the effects are not long lasting and do not seem to have clinical significance.

4. SYNDROMES OF SHORT STATURE

Many syndromes include short stature as a characteristic feature, and some also include SGA. Common conditions are described briefly later. Laurence-Moon, Biedl-Bardet, or Prader-Willi syndrome may combine obesity with short stature (as do the endocrine conditions, hypothyroidism, glucocorticoid excess, pseudohypoparathyroidism with Albright Hereditary Osteodystrophy (OMIM #103580), and GH deficiency). Moderately obese but otherwise normal children without these conditions tend to have slightly advanced bone age and advanced physiologic maturation with increased stature during childhood and early onset of puberty. Thus, short stature in an overweight child must be considered to have an organic cause until proven otherwise.

Turner Syndrome and Its Variants

Although classic Turner syndrome of 45, XO gonadal dysgenesis (see Chapter 14) is often correctly diagnosed, it is not always appreciated that any phenotypic female with short stature may have a variant of Turner syndrome. Thus, a karyotype determination should be performed for every short girl if no other cause for short stature is found, especially if puberty is delayed (see Chapter 15). The short stature of Turner syndrome is due to a mutation of the *short stature homeobox (SHOX)* gene on the short (p) arm in the pseudoautosomal region of the X chromosome (OMIM #312865). A mutation of the *SHOX* gene may also cause the Léri-Weill dyschondrosteosis form of short-limbed dwarfism (OMIM #127300).

Noonan Syndrome (Pseudo-Turner Syndrome) (OMIM #163950)

This syndrome shares several phenotypic characteristics of Turner syndrome, including short stature, webbed neck, low posterior hairline, and facial resemblance to Turner syndrome, but the karyotype is 46,XX in the female or 46,XY in the male with Noonan syndrome, and other features clearly differentiate it from Turner syndrome. For example, in Turner syndrome, there is characteristically left-sided heart disease and in Noonan syndrome right-sided heart disease. Noonan syndrome is an autosomal dominant disorder at gene locus 12q24 (see Chapter 14). GH therapy is approved by the FDA for Noonan syndrome to increase height. About half of patients with Noonan syndrome have a mutation of the protein tyrosine phosphatase nonreceptor type 11 (PTPN11) (OMIM #176876). These children have a decreased response to GH treatment and tend to have low IGF-I and ALS with normal IGFBP-3 levels. Noonan syndrome patients are prone to develop neoplasia and the PTPN11 mutation, among others, increases the risk adding a concern over GH treatment in them and underscores the need for surveillance for cancer.

Prader-Willi Syndrome (OMIM #176270)

This condition is characterized by poor intrauterine movement, acromicria (small hands and feet), developmental delay, and almond-shaped eyes along with infantile hypotonia. Short stature is common but not invariable. Although hypotonia limits feeding in infancy, later insatiable hunger develops and leads to extreme obesity. Glucose intolerance and delayed puberty are characteristic. This syndrome is due to deletion of the small nuclear riboprotein polypeptide N (SNRPN) on paternal chromosome 15 (q11-13), uniparental disomy of maternal chromosome 15, or methylation of this region of chromosome 15 of paternal origin. If a mutation of the same locus is derived from the mother, Angelman syndrome results. GH therapy is approved by the FDA for Prader-Willi syndrome to increase height, but the most important effects are improvement of body composition and muscle strength. There are several reported cases of the development of obstructive sleep apnea with GH treatment, which can be fatal, and so sleep patterns must be carefully monitored, and a sleep study must be performed, if there is question of sleep apnea before the administration of GH is begun.

Bardet-Biedl Syndrome

These autosomal recessive, but genetically heterogeneous conditions, are characterized by obesity, short stature, mental retardation, kidney dysfunction, polydactyly, and retinitis pigmentosa. Hypogonadotropic hypogonadism and primary hypogonadism have variously been reported in affected patients (#209900). There are presently 19 identified subtypes of this condition listed in Online Mendelian Inheritance in Man.

Autosomal Chromosome Disorders and Syndromes

Numerous other autosomal disorders and syndromes of dysmorphic children with or without developmental disorders are characterized by short stature. Often the key to diagnosis is the presence of several major or minor physical abnormalities that indicate the need for karyotype determination. Other abnormalities may include unusual body proportions, such as short extremities, leading to aberrant US:LS ratios, and arm spans quite discrepant from stature. Details of these syndromes can be found in the references listed at the end of the chapter.

Skeletal Dysplasias

There are more than 100 known types of genetic skeletal dysplasias (osteochondrodysplasias). Often they are noted at birth because of the presence of short limbs or trunk, but some are only diagnosed after a period of postnatal growth. The most common condition is autosomal dominant achondroplasia (OMIM #100800). This condition is characterized by short extremities in the proximal regions, a relatively large head with a prominent forehead due to frontal bossing and a depressed nasal bridge, and lumbar lordosis in later life. Adult height is decreased, with a mean of 132 cm for males and 123 cm for females. Intelligence is normal. Mutations of the tyrosine kinase domain of the *fibroblast growth factor receptor 3 (FGFR3)* gene locus 4p16.3 (OMIM #134934) have been identified in this condition. Limb lengthening operations are used to increase stature in a few centers but the techniques are complex, and complications appear to be frequent.

Height, height velocity, weight, and BMI curves from birth to 16 years of age are available for achondroplasia at http://pedinfo.org/growth.php. Children with achondroplasia who have received GH have in some instances demonstrated improved growth; however, atlanto-occipital dislocation is reported. The potential for abnormal brain growth and its relationship to aberrant skull shape mandates the caution that GH is not established therapy for this condition.

Hypochondroplasia (OMIM #146000) is manifested on a continuum from severe short-limbed dwarfism to apparent normal development until puberty, when there is an attenuated or absent pubertal growth spurt, leading to short adult stature. This disorder may be caused by an abnormal allele in the same gene causing achondroplasia (*FGFR3* at locus 4p16.3).

5. CHRONIC DISEASE

Severe chronic disease involving any organ system can cause poor growth in childhood and adolescence. In many cases, there are adequate historical or physical findings by the time of consultation to permit diagnosis. In some cases, however—most notably celiac disease and regional enteritis—short stature and decreased growth may precede obvious signs of malnutrition or gastrointestinal disease. In some cases, growth is only delayed and may spontaneously improve. In others, growth can be increased by improved nutrition; patients with gastrointestinal disease, kidney disease, or cancer may benefit from nocturnal parenteral nutritional infusions.

Cystic fibrosis combines several causes of growth failure: lung disease impairs oxygenation and predisposes to chronic infections, gastrointestinal disease decreases nutrient availability, and late-developing abnormalities of the endocrine pancreas cause diabetes mellitus. Children with cystic fibrosis experience decreased growth rates after 1 year of age following a normal birth size. The pubertal growth spurt is often decreased in magnitude and delayed in its timing; secondary sexual development may be delayed, especially in those with impaired pulmonary function. Study of growth in these patients allowed development of a cystic fibrosis specific growth chart and indicates that a reasonable outcome is an adult height in the 25th percentile. GH treatment in several studies demonstrated improved pulmonary function and increased growth and weight gain in cystic fibrosis. While growth charts for subjects with cystic fibrosis are available, use of standard charts for monitoring is also suggested.

Children with congestive heart failure, due to a variety of congenital heart diseases or acquired myocarditis, grow poorly unless successfully treated with medications or surgery. Patients with cyanotic heart disease and pulmonary hypertension appear to be most affected.

Celiac disease is present in about 1% of the population and may present initially with growth failure, but delayed puberty and menarche, osteopenia, osteoporosis, and other findings can arise. Early diagnosis can be made by determination of tissue transglutaminase antibodies, if IgA values are in the normal range while on a normal wheat-containing diet. However, a biopsy may still be required for diagnosis. On a gluten-free diet, patients experience catch-up growth. Adult height may still be impaired, depending on the duration of the period without treatment. Untreated patients with celiac disease have decreased serum IGF-I concentrations, presumably due to malnutrition, while IGF-I concentrations rise with dietary therapy. Thus, serum IGF-I in this condition, as in many with nutritional deficiencies, is not a reliable indicator of GH secretory status. Crohn's disease is associated with poor growth in 15% to 40% of cases. There is poor quality of evidence over the best manner to treat the condition and increase growth rate.

Patients with chronic hematologic diseases, such as sickle cell anemia or thalassemia, often have poor growth, delayed puberty, and short adult stature: iron deposition may itself cause endocrine complications. Juvenile rheumatoid arthritis may compromise growth before or after therapy with glucocorticoids. GH treatment is reported to increase the growth rate of these children. Hypophosphatemic vitamin D-resistant rickets usually leads to short adult stature, but treatment with 1,25-hydroxyvitamin D and oral phosphate in most cases will improve bone growth as well as increase adult stature. Chronic renal disease is known to interfere with growth, but increased growth rate occurs with improved nutrition. GH therapy is approved for affected children who still grow poorly.

Proximal or distal renal tubular acidosis (RTA) may cause short stature. Proximal RTA demonstrates bicarbonate wasting at normal or low plasma bicarbonate concentrations; patients have hypokalemia, alkaline urine pH, severe bicarbonaturia, and later, acidemia. The condition may be inherited, sporadic, or secondary to many metabolic or medication-induced disorders. Distal RTA is caused by inability to acidify the urine; it may occur in sporadic or familial patterns or be acquired as a result of metabolic disorders or medication. Distal RTA is characterized by hypokalemia, hypercalciuria, and occasional hypocalcemia. The administration of bicarbonate is the primary therapy for proximal RTA, and proper treatment can substantially improve growth rate.

Obstructive sleep apnea is associated with poor growth. The amount of energy expended during sleep in children with sleep apnea appears to limit weight and length gain, a pattern which reverses with the resolution of the obstruction. Obstructive sleep apnea is also associated with obesity and Prader-Willi syndrome. Diagnosis is made by polysomnography.

6. MALNUTRITION

Malnutrition (other than that associated with chronic disease) is the most common cause of short stature worldwide and is the cause of much short stature in the developing world. Diagnosis in the developed world is based on historical and physical findings, particularly the dietary history. Food faddism and anorexia nervosa—as well as excessive voluntary dieting—can cause poor growth. Infections with parasites, such as *Ascaris lumbricoides* or *Giardia lamblia*, can decrease growth and are a principal cause of short stature in the developing world.

Specific nutritional deficiencies can have particular effects on growth. For example, severe iron deficiency can cause a thin habitus as well as growth retardation. Zinc deficiency can cause anorexia, decreased growth, delayed puberty, developmental problems, hair loss, diarrhea, impotence, eye and skin abnormalities, and taste changes leading to weight loss. Acrodermatitis enteropathica is a rash giving a visual clue to Zn deficiency. It arises usually in the presence of chronic systemic disease or infection. Children with nutritional deficiencies characteristically demonstrate failure of weight gain before growth rate decreases, and before weight for height decreases. This is in contrast to many endocrine causes of poor growth, where weight for height remains in the normal or high range. This simple rule often determines whether nutritional or endocrine evaluations are most appropriate. There are no simple laboratory tests for diagnosis of malnutrition. Serum IGF-I concentrations are low in malnutrition, as they are in GH deficiency. This distinction is important since misdiagnosing GH deficiency instead of malnutrition would be tragic as well as costly.

7. MEDICATIONS

Children with hyperactivity disorders (or those incorrectly diagnosed as such) are frequently managed with chronic methylphenidate administration or similar medication. These agents can decrease weight gain by decreasing appetite and can lower growth rate, albeit inconsistently. These drugs must be used in moderation and only in children who definitely respond to them during careful evaluation and follow-up.

Exogenous glucocorticoids are a potent cause of poor growth (discussed later), as are excessive endogenous glucocorticoids.

SHORT STATURE DUE TO ENDOCRINE DISORDERS

Using the conservative criteria of height (<3rd percentile) and growth velocity (<5 cm/y for inclusion in the study), the incidence of endocrine disease in 114,881 Utah children who met these cutoff results was 5%, with a higher incidence in boys than girls by a ratio of more than 2.5:1. In this population, 48% of the children with Turner syndrome or GH deficiency were not diagnosed prior to the careful evaluation afforded by this study.

1. GROWTH HORMONE DEFICIENCY AND ITS VARIANTS

The incidence of GH deficiency is estimated to be between 1:4000 and 1:3500, so the disorder should not be considered rare.

There may be abnormalities at various levels of the hypothalamic-pituitary, GH-IGF-I axis. Most patients with idiopathic GH deficiency lack GHRH. One autopsied GH-deficient patient had an adequate number of pituitary somatotrophs that contained considerable GH stores. Thus, the pituitary gland produced GH, but it could not be released. Long-term treatment of such patients with GHRH can cause GH release and increase growth, but this therapy is not presently in use. Patients with pituitary tumors or those rare patients with congenital absence of the pituitary gland lack somatotrophs. Several kindreds have been described that lack various regions of the *GH* gene (responsible for producing GH). Alternatively, gene defects responsible for the embryogenesis of the pituitary gland may cause multiple pituitary deficiencies. Absence of the *PIT1* gene encoding a pituitary-specific transcription factor causes deficient GH, TSH, and prolactin synthesis and secretion. Mutations of the prophet of PIT1 (*PROP1*) gene cause deficiencies of GH, TSH, FSH, LH, and ACTH production.

Congenital Growth Hormone Deficiency

Congenital GH deficiency presents with slightly decreased birth length (−1 SD), but the growth rate decreases in some cases strikingly soon after birth. The disorder is identified by careful measurement in the first year and becomes more obvious by 1 to 2 years of age. Patients with classic GH deficiency have short stature, increased fat mass leading to a chubby or cherubic appearance with immature facial appearance, immature high-pitched voice, and delay in skeletal maturation. Less severe forms of partial

GH deficiency are described with few abnormal characteristics apart from short stature, decreased growth rate, and delayed bone age. GH-deficient patients lack the lipolytic effects of GH, partially accounting for the pudgy appearance. There is a higher incidence of hyperlipidemia with elevated total cholesterol and low-density lipoprotein (LDL) cholesterol in GH deficiency, and longitudinal studies demonstrate increases in high-density lipoprotein (HDL) cholesterol levels with GH treatment. Males with GH deficiency may have microphallus (penis <2 cm in length at birth), especially if the condition is accompanied by gonadotropin-releasing hormone (GnRH) deficiency (Figure 6–8). GH

FIGURE 6–8 A 12-month-old boy with congenital hypopituitarism. He had hypoglycemic seizures at 12 hours of age. At 1 year, he had another hypoglycemic seizure (plasma glucose, 25 mg/dL) associated with an episode of otitis media, and it was noted that his penis was extremely small. At 12 months, body length was 66.5 cm (−2 SD) and weight was 8.5 kg (−3 SD). The penis was less than 1.5 cm long, and both testes were descended (each 1 cm in diameter). Plasma GH did not rise above 1 ng/mL after arginine and levodopa testing (no insulin tolerance test was performed because of the history of hypoglycemia). LH rose very little after administration of GnRH (gonadorelin), 100 μg. Serum thyroxine was low (T_4, 6.6 μg/dL; T_4 index, 1.5), and after administration of 200 μg of protirelin (TRH), serum TSH rose with a delayed peak characteristic of tertiary hypothyroidism. Plasma ACTH rose only to 53 pg/mL after metyrapone. Thus, the patient had multiple defects in the hypothalamic-pituitary axis including decreased secretion of GH, ACTH, and TSH due to deficient secretion of hypothalamic hormones. He was given six doses of 2000 units each of human chorionic gonadotropin (hCG) intramuscularly over 2 weeks, and plasma testosterone rose to 62 ng/dL, indicating normal testicular function. He was then treated with 25 mg of testosterone enanthate every month for 3 months, and his phallus enlarged to 3.5 × 1.2 cm without significant advancement of bone age. With hGH therapy (0.05 mg/kg intramuscularly every other day), he grew at a greater than normal rate for 12 months (catch-up growth), and growth then continued at a normal rate.

deficiency in the neonate or child can also lead to symptomatic hypoglycemia and seizures; if ACTH deficiency is also present, hypoglycemia is usually more severe. The differential diagnosis of neonatal hypoglycemia in a full-term infant who has not sustained birth trauma must include neonatal hypopituitarism. If microphallus (in a male subject), optic hypoplasia, or some other midline facial or CNS defect is noted, the diagnosis of congenital GH deficiency is more likely (see later). Congenital GH deficiency is also correlated with breech delivery. Intelligence is normal in GH deficiency unless repeated or severe hypoglycemia is present or a significant anatomic defect has compromised brain development. When thyrotropin-releasing hormone (TRH) deficiency is also present, there may be additional signs of hypothyroidism. Secondary or tertiary congenital hypothyroidism is not usually associated with physical findings of cretinism or developmental delay as is congenital primary hypothyroidism, but a few cases of isolated TRH deficiency and severe mental retardation are reported.

Congenital GH deficiency may present with midline anatomic defects. Optic hypoplasia with visual defects ranging from nystagmus to blindness is found with variable hypothalamic endocrinopathies in 71.7% of one series: 64.1% of subjects had GH axis abnormalities, 48.5% hyperprolactinemia, 34.9% hypothyroidism, 17.1% adrenal insufficiency, and 4.3% diabetes insipidus (DI) in this group of 47 subjects. About half of patients with optic hypoplasia have absence of the septum pellucidum on computed tomography (CT) or magnetic resonance imaging (MRI), leading to the diagnosis of septo-optic dysplasia. Septo-optic dysplasia is most often sporadic in occurrence but some affected individuals are reported with mutations of the *homeobox* gene expressed in ES cells (*HESX1*) (OMIM #601802) and septo-optic dysplasia (OMIM #182230). Cleft palate or other forms of oral dysraphism are associated with GH deficiency in about 7% of cases. Such children may need nutritional support to improve their growth. An unusual midline defect associated with GH deficiency is described in children with a single maxillary incisor.

Congenital absence of the pituitary gland, which occurs in an autosomal recessive pattern, leads to severe hypopituitarism with hypoglycemia. Affected patients have shallow development of or absence of the sella turcica. This defect is quite rare but clinically devastating due to ACTH deficiency if treatment is delayed. This is the most common MRI manifestation of *PROP1* gene mutation (OMIM #601538).

Hereditary GH deficiency is described in several different mutations. Various genetic defects of the *GHN* gene (17q22-24) occur in affected families. Isolated type 1A GH deficiency (IGH-DIA OMIM #262400) is inherited in an autosomal recessive pattern. Patients have deletions, frameshifts, and nonsense mutations in the *GH* gene. Unlike those with classic sporadic GH deficiency, some of these children are reported with significantly shortened birth lengths. Patients with absent or abnormal *GH* genes initially respond to exogenous human GH (hGH) administration, but some soon develop high antibody titers that eliminate the effect of therapy. Patients with high titers of blocking antibodies are reported to benefit from IGF-I therapy in place of GH therapy. Isolated GH deficiency (IGHD) type 1B (OMIM #612781) patients have autosomal recessive splice site mutations

and incomplete GH deficiency and are less severely affected. Type 2 (IGHD2) (OMIM #173100) patients have autosomal dominant GH deficiency due to splice site or missense mutations. Type 2 patients have X-linked GH deficiency often associated with hypogammaglobulinemia.

A few patients are described with abnormalities of the *GHRH* gene. Mutations in pituitary transcription factors can lead to various combinations of pituitary hormone deficiencies as noted earlier. Mutations in *PIT1/POU1F1* (POU class 1 homeobox 1) (OMIM #173110) lead to GH, PRL, and TSH deficiencies. Mutations in *PROP1* (Prophet of PIT1, paired-like homeodomain transcription factor) (OMIM #601538) lead to GH, PRL, TSH, LH, FSH, and sometimes ACTH deficiencies. Mutations in *HESX1* lead to GH, PRL, TSH, LH, FSH, ACTH, IGHD, and CPHD deficiencies.

Acquired Growth Hormone Deficiency

Onset of GH deficiency in late childhood or adolescence, particularly if accompanied by other pituitary hormone deficiencies, is ominous and may be due to a hypothalamic-pituitary tumor. The development of posterior pituitary deficiency, in addition to anterior pituitary deficiency, makes a tumor even more likely. The empty sella syndrome is more frequently associated with hypothalamic-pituitary abnormalities in childhood than in adulthood; thus, GH deficiency may be found in affected patients.

Some patients, chiefly boys with constitutional delay in growth and adolescence, may have transient GH deficiency on testing before the onset of puberty. When serum testosterone concentrations begin to increase in these patients, GH secretion and growth rate also increase. This transient state may incorrectly suggest *bona fide* GH deficiency but does not require therapy. A priming dose of estrogen is sometimes invoked to increase GH secretion maximally so that spurious GH deficiency is not diagnosed spuriously. CNS conditions that cause acquired GH deficiency (eg, craniopharyngiomas, germinomas, gliomas, histiocytosis X) are described in Chapter 4. It is remarkable that after craniopharyngioma removal, some patients, mainly obese subjects, continue to grow quite well in spite of the absence of GH secretion. This persistent growth appears to be caused by hyperinsulinemia.

Cranial irradiation of the hypothalamic-pituitary region to treat CNS tumors or acute lymphoblastic leukemia may result in GH deficiency starting approximately 12 to 18 months later, owing to radiation-induced hypothalamic (or perhaps pituitary) damage. Higher doses of irradiation, such as the 24-Gy regimen previously used for the treatment of CNS leukemia, have greater effect (adult height may be as much as 1.7 SD below the mean) than the lower (eg, 18 Gy) regimens and higher doses are more likely to cause TSH, ACTH, and gonadotropin deficiency as well as hyperprolactinemia or even precocious puberty. Girls treated at an early age with this lower regimen still appear to be at risk of growth failure. All children must be carefully observed for growth failure after irradiation since growth failure may occur years later. If these patients receive spinal irradiation, upper body growth may also be impaired, causing a decreased US-LS ratio and a further

tendency to short stature. Abdominal irradiation for Wilms tumor may also lead to decreased spinal growth (estimated loss of 10 cm height from megavoltage therapy at 1 year of age, and 7 cm from treatment at 5 years of age). Others receiving gonadal irradiation (or chemotherapy) have impaired gonadal function, lack onset or progression of puberty, and/or have diminished or absent pubertal growth spurt. Chemotherapy for acute lymphocytic leukemia without irradiation may also lead to GH deficiency, so follow-up of growth after treatment for cancer is always necessary.

CNS trauma is well established as a cause of hypopituitarism in adults. Cross sectional studies in children reveal both high and low rates of subsequent hypopituitarism after head trauma, but the rare prospective studies demonstrate lower risk in children than in adults.

Other Types of GH Dysfunction

Primary IGF-I deficiency is due to GH insensitivity (Laron syndrome and its variants (OMIM #262500)). These disorders reflect GH receptor or post-receptor defects that are inherited in autosomal recessive fashion. The soluble GH-binding protein (GHBP) found in the circulation arises from the extracellular portion of the GH receptor, and since they derive from the same gene, circulating GHBP reflects the abundance of GH receptors. Patients with decreased or absent GH receptors have decreased serum GHBP levels, whereas those with post-receptor defects have normal GHBP concentrations. Affected children are found throughout the world, including Israel, where the syndrome was first reported, and Ecuador, where several generations of a large kindred were studied in great detail. Defects in various kindreds include nonsense mutations, deletions, RNA processing defects, and translational stop codons. GH/JAK-STAT axis signal-transduction impairment leads to short stature, when this intracellular system fails to activate in response to receptor occupancy by the GH ligand. Defects in the dimerization of the GH receptors, a required step in GH action, also lead to short stature. Serum GH is elevated in all forms of GH resistance, due to decreased or absent IGF-I, which results in lack of negative feedback inhibition. Patients are short at birth, confirming the importance of IGF-I in fetal growth (demonstrated previously in murine *IGF-I* gene knockout studies). About one-third have hypoglycemia, and half of boys have microphallus. The condition does not respond to GH treatment. Patients treated with recombinant IGF-I grow at an improved rate but do not respond quite as well to IGF-I as GH-deficient children do to GH treatment, indicating that GH may have a direct role in fostering growth above and beyond that conferred by IGF-I.

Other forms of GH resistance are described, but the majority of patients with disorders of the GH axis have abnormalities of GH secretion, not action. Very short, poorly growing children with delayed skeletal maturation, normal GH and IGF-I values, and no signs of organic disease have responded to GH therapy with increased growth rates equal to those of patients with bona fide GH deficiency. These patients may have a variation of constitutional delay in growth or genetic short stature, but a subtle abnormality of GH secretion or action is possible.

Pygmies (OMIM #265850) have normal serum GH, low IGF-I after puberty, and normal IGF-II concentrations. They have a congenital inability to raise IGF-I concentrations after puberty, which has greater importance in stimulating growth than IGF-II. Pygmy children are reported to lack a pubertal growth spurt, suggesting that IGF-I is essential to attain a normal peak growth velocity. Efe pygmies, the shortest of the pygmies, are significantly smaller at birth than neighboring Africans who are not pygmies, and their growth is slower throughout childhood, leading to statures displaced progressively below the mean. A few patients are reported with defects of the *IGF-I* gene or with deficiency of the IGF-I receptor (IGF-IR) (OMIM #147370) and extreme short stature that is not responsive to IGF-I. Intrauterine growth deficiency, microcephaly, developmental delay, and other psychological findings are reported in these cases. Why do certain normal children, perhaps within a short family, have stature significantly lower than the mean? There is no definite answer to this persistent question, but some patients have decreased serum GHBP concentration, which suggests a decrease in GH receptors in these children. A minority of short, poorly growing children have definable genetic abnormalities of their GH receptors. Genome Wide Association studies are uncovering various genetic influences on normal and pathologic stature. Short stature is the final common pathway of numerous biochemical abnormalities.

Adults who had GH deficiency in childhood or adolescence have decreased bone mass compared with normals even when bone mass is corrected for their smaller size. There is progressive bone loss in adults who are GH deficient even if bone density was improved with childhood therapy; GH is approved for adults with GH deficiency and can reverse this trend (see Chapter 4).

Diagnosis of GH Deficiency

Because basal values of serum GH are low in normal children and GH-deficient patients alike, the diagnosis of GH deficiency has classically rested on demonstration of an inadequate rise of serum GH after provocative stimuli or on some other measure of GH secretion. This process is complicated because different radioimmunoassay systems vary widely in their measurements of GH in the same blood sample (eg, a result on a single sample may be above 10 ng/mL in one assay but only 6 ng/mL in another). The physician must be familiar with the standards of the laboratory being used. Most insurance companies and state agencies accept inability of GH to rise above 10 ng/mL with stimulation as diagnostic of GH deficiency.

Another complicating factor is the state of pubertal development. Prepubertal children secrete less GH than pubertal subjects and, especially as they approach the onset of puberty, may have sufficiently reduced GH secretion to suggest falsely *bona fide* GH deficiency. This factor is sometimes addressed by administering a dose of estrogen to such subjects before testing. The very concept of GH testing provides a further complication. GH is released in episodic pulses. Although a patient who does not secrete GH in response to standard challenges is generally considered to be classically GH-deficient, a normal GH response to these tests may not rule out the efficacy of GH treatment. Testing should occur after

an overnight fast; carbohydrate or fat ingestion suppresses the GH response. Obesity suppresses GH secretion, and an overweight or obese child may falsely appear to have GH deficiency. Even within the normal range, variations of BMI affect peak GH after stimulation.

Because 10% or more of healthy children do not have an adequate rise in GH with one test of GH reserve, at least two methods of assessing GH reserve are necessary before the diagnosis of classic GH deficiency is assigned. Of course, if GH rises above 10 ng/mL in a single test, classic GH deficiency is eliminated. Serum GH values should rise after 10 minutes of vigorous exercise; this is used as a screening test. After an overnight fast, GH levels should rise in response to arginine infusion (0.5 g/kg body weight [up to 20 g] over 30 minutes), oral levodopa (125 mg for up to 15 kg body weight, 250 mg for up to 35 kg, or 500 mg for >35 kg), or clonidine (0.1 mg/m^2 orally). Side effects of levodopa include nausea; those of clonidine include some drop in blood pressure and drowsiness. Glucagon stimulation testing is used to determine both GH and ACTH secretory ability. It is accomplished by administration of 30 μg/kg glucagon (maximum 1 mg) and collecting GH samples at 0, 30, 60, 90, 120, 150, and 180 minutes afterwards; nausea and hyperglycemia are possible side effects.

The insulin tolerance test is another way to assess GH reserve but can be dangerous to perform and is rarely invoked. GH levels rise after acute hypoglycemia due to insulin administration; however, this test carries a risk of seizure if the blood glucose level drops excessively. An insulin tolerance test may be performed if a 10% to 25% dextrose infusion is available for emergency administration in the face of hypoglycemic coma or seizure and if the following conditions are satisfied: (1) an intravenous infusion line with heparin lock or low-rate saline infusion is available before the test begins, (2) the patient can be continuously observed by a physician, and (3) the patient has no history of hypoglycemic seizures. The patient must have a normal glucose concentration at the beginning of the test in the morning after an overnight fast (water intake is acceptable). Regular insulin, 0.075 to 0.1 U/kg in saline, may be given as an intravenous bolus. In 20 to 40 minutes, a 50% drop in blood glucose will occur, and a rise in serum GH and cortisol and ACTH should follow. Serum glucose should be monitored, and an intravenous line must be maintained for emergency dextrose infusion in case the patient becomes unconscious or has a hypoglycemic seizure. If dextrose infusion is necessary, it is imperative that blood glucose not be raised far above the normal range, because hyperosmolality has been reported from overzealous glucose replacement; undiluted 50% dextrose should not be used (see Chapter 4). This is a dangerous test and is rarely indicated!

A family of synthetic penta- and hexapeptides called GH-releasing peptides (GHRPs) stimulate GH secretion in normal individuals and in GH-deficient subjects. GHRPs act via ghrelin receptors of the hypothalamus that are different from the GH-releasing factor (GHRF) receptors, and their effects are additive to that of GHRF. Ghrelin is a gastrointestinal-derived peptide that naturally binds to these receptors in the hypothalamic ventromedial nucleus, arcuate nucleus and ventral tegmental area (dopaminergic neurons), causing GH secretion, it also stimulates appetite and is classified as an orexigenic agent. Recently, mutations in the

GH secretagogue receptor (GHSR) that binds GHRPs and ghrelin were found in children with short stature; treatment with GH increased growth rate in these children.

Patients who respond to the pharmacologic stimuli noted earlier, but not to physiologic stimuli, such as exercise or sleep, are said to have neurosecretory dysfunction. These patients have decreased 24-hour secretion of GH (or integrated concentrations of GH) compared with healthy subjects, patterns similar to those observed in GH-deficient patients. It is not clear how frequently this condition is encountered.

This long discussion of the interpretation of GH after secretagogue testing brings into question the very standard for the diagnosis of GH deficiency. It is clear that pharmacologic testing cannot always determine which patients truly need GH therapy, and many authorities suggest that we abandon such dynamic testing in favor of measurements of IGF-I and IGFBP-3, although dynamic GH testing may still be required by insurance plans. Serum IGF-I values are low in most GH-deficient subjects, but, as noted earlier, some short patients with normal serum IGF-I concentrations may require GH treatment to improve growth rate. Moreover, starvation lowers IGF-I values in healthy children and incorrectly suggests GH deficiency. Children with psychosocial dwarfism—who need family therapy or foster home placement rather than GH therapy—have low GH and IGF-I concentrations and may falsely appear to have GH deficiency. Likewise, patients with constitutional delay in adolescence have low IGF-I values for chronologic age, but normal values for skeletal age, and may have temporarily decreased GH response to secretagogues. Thus, IGF-I determinations are not infallible in the diagnosis of GH deficiency. They must be interpreted with regard to nutrition, psychosocial status, and skeletal ages. IGFBP-3 is GH-dependent, and if its concentration is also low, it provides stronger evidence of GH deficiency than does the IGF-I determination alone.

The Growth Hormone Research Society produced criteria that attempt to deal with the diagnosis of GH deficiency in childhood in spite of the uncertainty of the methods. These criteria use clinical findings of various conditions associated with GH deficiency, the severity of short stature, and the degree and duration of decreased growth velocity to identify individuals that may have GH deficiency. The guidelines and diagnostic considerations in this chapter include most of the GH Society criteria. (See "Consensus guidelines" reference in the Short Stature section at the end of this chapter for details of the Growth Hormone Research Society statement.) A 3- to 6-month therapeutic trial of GH therapy may be necessary to determine growth response; if growth increases more than 2 cm/y, it is likely that the child will benefit from GH treatment, no matter what the tests originally showed.

Treatment of GH Deficiency

A. GH replacement   Before 1986, the only available method of treatment for GH deficiency was replacement therapy with hGH derived from cadaver donors. In 1985 and thereafter, Creutzfeldt-Jakob disease, a degenerative neurologic disease rare in patients so young, was diagnosed in some patients who had received natural hGH up to 10 to 15 years before. Because of

the possibility that prions contaminating donor pituitary glands were transmitted to the GH-deficient patients, causing their deaths, natural GH from all sources was removed from distribution. Recombinant hGH now accounts for the world's current supply.

Commercial hGH has the 191-amino acid natural sequence. hGH is now available in virtually unlimited amounts, allowing innovative treatment regimens not previously possible owing to scarce supplies. The potential for abuse of hGH in athletes or in children of normal size whose parents wish them to be taller than average, however, must now be addressed.

Growth disturbances due to disorders of GH release or action are shown in Table 6–2. GH-deficient children require biosynthetic somatropin (natural sequence hGH) at a dose of 0.18–0.3 mg/kg/wk administered in one subcutaneous dose per day 6 or 7 times per week during the period of active growth before epiphyseal fusion. An increased dose is approved by the FDA for use during puberty. The increase in growth rate (Figures 6–9, 6–10, and 6–11) is most marked during the first year of therapy. Older children do not respond as well and may require larger doses. Higher doses, up to double the standard starting dose, are approved by the FDA for use in puberty, but there are varying reports of the effect of these higher doses on adult height as, by far, most of the effect of GH on adult height is exerted in the years before puberty. GH does not increase growth rate without adequate nutrition and euthyroid status. During the roughly 50 years since the first use of GH in children, long-term effects are reported in several series. If only the children most recently treated with recombinant hGH are considered, the mean adult height was 1.4 SD below the mean, a significant improvement over the –2.9 SD mean height at the start of therapy but not a true normalization of height in most patients. With earlier diagnosis and treatment, using new pubertal dosing schedules, adult height can reach genetic potential.

TABLE 6–2 Level of defect in growth.

Site of Defect	Clinical Condition
Hypothalamus	Idiopathic GH deficiency due to decreased GHRH secretion; hypothalamic tumors or congenital defects
Pituitary gland	Dysplasia, trauma, surgery, or tumor of the pituitary gland; defect in GH gene or in pituitary transcription factors
Sites of IGF production	Primary IGF-I deficiency: GH receptor defect (Laron dwarfism with high GH and low IGF concentrations) ALS deficiency Growth hormone/JAK-STAT axis signal transduction defect Pygmies with normal GH, low IGF-I, and normal IGF-II concentrations
Cartilage	Glucocorticoid-induced growth failure Resistance to IGF-I

Monitoring of GH replacement is mainly accomplished by measuring growth rate and annually assessing bone age advancement. Serum IGF-I and IGFBP-3 will rise with successful therapy while GHBP will not change appreciably. Controlled clinical studies reported the utility of titrating the dose of GH to restore serum IGF-I to the high-normal range, monitoring serum IGF-I levels during clinical treatment. There is concern if the IGF-I levels rise more than two SDs above the mean and, if so, the GH dose is decreased. Serum bone-specific alkaline phosphatase rises with successful therapy. Urinary hydroxyproline, deoxypyridinoline, and galactosyl-hydroxylysine reflect growth rate and are used in clinical studies to reflect increased growth rate with therapy.

Antibodies to GH may be present in measurable quantities in the serum of children receiving GH. However, a high titer of blocking antibodies with significant binding capacity is rare except in patients with absence or abnormality of GH genes. Only a few patients are reported to have temporarily ceased growing because of antibody formation. GH exerts anti-insulin effects. Although clinical diabetes is not a likely result of GH therapy, the long-term effects of a small rise in glucose in an otherwise healthy child are unknown. If a tendency toward diabetes is already present, GH may cause the onset of clinical manifestations more quickly. Another potential risk is the rare tendency to develop slipped capital femoral epiphyses in children receiving GH therapy; slipped capital femoral epiphyses occur at times of increased growth rate. Recent data have weakened the link between slipped capital femoral epiphyses and GH therapy, but the final import of the relationship is not yet clear. Slipped capital femoral epiphyses, if associated with endocrinopathies, are most common in treated hypothyroid patients (50% one series of 80 episodes of slipped capital femoral epiphyses), followed by treated GH-deficient patients (25% of the series). This condition may occur bilaterally, and prophylactic treatment of the nonaffected side is recommended by several authorities. Pseudotumor cerebri may rarely occur with GH therapy, is usually associated with severe headache and may be more common in obese individuals receiving GH treatment. It is reported to reverse after cessation of GH therapy, but if allowed to continue, it may impair vision due to pressure on the optic nerve and cause severe complications. Organomegaly and skeletal changes like those found in acromegaly are other theoretical side effects of excessive GH therapy but do not occur with standard doses. Furthermore, prepubertal gynecomastia is reported with GH therapy.

Lack of compliance with GH therapy is a frequent cause of poor growth leading to undertreatment. Reported non-compliance is in the range of 33%. Lack of normalization of IGF-I with treatment is an indication of noncompliance.

The discovery of leukemia in young adults previously treated with GH was worrisome, but no cause and effect relationship has been established, and GH treatment is not considered a cause of leukemia. GH does not increase the recurrence rate of tumors existing before therapy. Thus, patients with craniopharyngiomas, for example, may receive GH, if indicated, after the disease is clinically stable, without significant worry that the GH will precipitate a recurrence. Clinicians usually wait 1 year after
FIGURE 6–9 Examples of abnormal growth charts. Squares represent the growth pattern of a child (such as patient **A** in Figure 6–11) with precocious sexual development and early excessive growth leading to premature closure of the epiphyses and cessation of growth. Circles represent growth of a boy (such as patient **B** in Figure 6–11) with GH deficiency who showed progressively poorer growth until 6 years of age, when he was treated with hGH (arrow), after which catch-up growth occurred. The curves describe SDs from the mean.

completion of tumor therapy before starting patients on GH therapy, but doing so is not a requirement. There are reports of a small increase in risk of colonic carcinoma decades after natural GH treatment in GH-deficient children, but no such information on long-term follow-up of children treated with recombinant hGH is available. GH deficiency is associated with an adverse lipid profile with elevated LDL cholesterol and decreased HDL cholesterol in addition to an increased BMI; GH-deficient adolescents treated with GH develop these findings within a few years after discontinuation of GH therapy. Low-dose GH therapy is now approved for use in adults with childhood-onset GH deficiency and is said to forestall these metabolic changes. Further, adult GH therapy maintains muscle strength and bone density in GH-deficient adults. One can, therefore, inform the parents of a child with GH deficiency that the patient may still benefit from GH therapy even after he or she stops growing if profound GH deficiency remains after repeat testing once off GH for at least 1 month.

GH has been combined with other substances to increase its impact on height. In patients who were diagnosed late, have entered puberty, and appear to have limited time to respond to GH before epiphyseal fusion causes the cessation of growth, a GnRH agonist has been used to delay epiphyseal fusion in clinical trials with varying success, but this was not recommended by a consensus conference on the use of GnRH agonist therapy, due to lack of strong evidence of effectiveness. This off-label use is not yet established as safe and effective. Aromatase inhibitors have been combined with GH in some clinical studies, but this is not yet regular clinical practice; there was a reported effect of decreasing bone age advancement, while allowing increased growth and height.

There are other conditions for which the FDA has approved the use of GH. GH therapy will increase adult height in Turner syndrome to an average of 5.1 cm if started early enough; the addition of low-dose oxandrolone is reported to further increase
FIGURE 6–10 Two examples of abnormal growth plotted on a height velocity chart simplified from the charts in Figure 6–3. **A**. The plot is taken from the data recorded as squares in Figure 6–9, describing a patient with precocious puberty such as patient **A** in Figure 6–11, with premature epiphysial closure, and cessation of growth. **B**. The plot is taken from the data recorded as circles in Figure 6–9, describing a patient with GH deficiency (such as patient **B** in Figure 6–11) who was treated with hGH (arrow) at age 6. Initial catch-up growth is noted for 2 years, with a lower (but normal) velocity of growth following. These charts display growth rate over 6 month growth intervals rather than 12-month intervals as shown on Figures 6–3 and 6–4.
FIGURE 6–11 Two boys demonstrating extremes of growth. The boy at left in each photograph **(A)** has precocious puberty due to a CNS lesion. At 4½ years, he was 125.1 cm tall, which is 4.5 SDs above the mean. (The mean height for a 4-year-old is 101.5 cm.) His testes measured 2 × 3.5 cm each, his penis 9.8 × 2.8 cm (all pubertal measurements). He was muscular and had acne and a deep voice. His bone age was 10 years, the testosterone level was 480 ng/dL, and the LH rose after 100 μg of GnRH (gonadorelin) to a pubertal response. His brain CT scan revealed a hamartoma of the tuber cinereum. The boy at right **(B)** at 6 years of age was 85 cm tall, which is more than 5 SD below the mean. He had the classic physical and historical characteristics of idiopathic GH deficiency, including early growth failure and a cherubic appearance. His plasma GH values were nondetectable and did not rise after provocative testing.

growth rate. Estrogen is used to promote feminization and maintain bone mineral density; the optimal time to initiate treatment with estrogen should be individualized based on bone age, height, and psychological factors. Usually estrogen is administered during the adolescent years in low doses and only after the normal age of onset of puberty is reached to preserve maximal adult height, although earlier initiation of therapy is gaining credence (see Chapter 15).

Recently, French researchers released data from a large ongoing prospective study and reported an increased risk of hemorrhagic stroke in early adulthood after hGH therapy during childhood and adolescence. However the cause and effect of hGH treatment on stroke remain to be established. The FDA is presently investigating these data, but findings have not changed clinical practice in the United States, and the FDA has not suggested that the clinical use of GH change. Present evidence does not support an increase in all cause mortality or neoplasia from hGH treatment.

In the most successful series of children with SGA treated with hGH, the agent increased adult height between 2.0 SD and 2.7 SD. Girls with Turner syndrome treated with hGH reach adult height of more than 150 cm, an increase from the average untreated height which is about 144 cm. When treatment starts at or before 4 years, an adult height is achieved in the normal range.

Treatment with GH is approved for chronic renal disease in childhood. GH increases growth rate above the untreated state without excessive advancement in bone age. Prader-Willi syndrome may also be treated with GH to increase growth rate, lean tissue mass, and bone density. A recent study indicated that parental education exerted the most significant effect on body composition in these children. However, there are reports that patients with Prader-Willi syndrome have died of obstructive sleep apnea following GH treatment, demonstrating a need for sleep studies to exclude sleep apnea before initiating treatment and constant surveillance after treatment has been initiated. The treatment of Noonan syndrome is described earlier. In general, males are more often treated with GH than females in the United States, but this is not the case in other developed countries.

The FDA has approved the use of GH in otherwise normal children, whose stature is below 2.25 SDs for age and who are predicted to fall short of reaching normal adult height (<1 percentile of adult height). There may be pressure for treatment of children predicted to be taller than these guidelines from parents, but the FDA approval is for specific indications. While GH may increase the height of such severely affected children, it should not be used for a child whose predicted adult height is in the normal range. Treatment costs $30,000 to $40,000 per year or about $35,000 per cm gained. In the United States, males are treated more often than females, while the ratio is more equal in other countries, presumably due to social/cultural issues.

GHRH has been isolated, sequenced, and synthesized. It is available for use in diagnosis and treatment. GH-deficient patients demonstrate lower or absent GH secretion after administration of

GHRH. However, episodic doses of GHRH can restore GH secretion, IGF-I production, and growth in children with idiopathic GH deficiency. The ability of GHRH administration to stimulate pituitary GH secretion further supports the concept that idiopathic GH deficiency is primarily a disease of the hypothalamus, not of the pituitary gland.

IGF-I is now produced by recombinant DNA technology. IGF-I is useful in the treatment of certain types of short stature, particularly Laron dwarfism (and perhaps for African pygmies, should treatment be desired) where neither GH nor any other treatment is effective. IGF-I has been studied clinically for more than 12 years. Side effects, such as hypoglycemia (observed in 49% of treated subjects), injection site lipohypertrophy (32%), and tonsillar/adenoidal hypertrophy (22%), are common but not said to be severe. However, there is concern among some authorities as to the safety of this therapy.

B. Psychologic management and outcome   Research into the psychologic outcome of patients with short stature is flawed by lack of consistent methods of investigation and lack of controlled studies, but some results are of interest.

Studies vary in their conclusions, as to whether short stature is harmful to a child's psychologic development or not, and whether, by inference, GH is helpful in improving the child's psychologic functioning. Children with GH deficiency are the most extensively studied; earlier investigations suggested that they have more passive personality traits than do healthy children, may have delayed emotional maturity, and suffer from infantilization from parents, teachers, and peers. Many of these children have been held back in school because of their size without regard to their academic abilities. Some patients retain a body image of short stature even after normal height has been achieved with treatment. More recent studies challenge these views and suggest that self-image in children with height below the 5th percentile, who do not have GH deficiency, is closely comparable to a population of children with normal height. These findings may not be representative of the patient population discussed earlier in that a normal ambulatory population of *short* children may differ from the selected group that seeks medical attention. The data suggest that short stature itself is not cause for grave psychologic concern, and such concerns should not be used to justify GH therapy. We cannot avoid the fact that our *heightist* society values physical stature and equates it with the potential for success, a perception that is not lost on the children with short stature and their parents. A supportive environment in which they are not allowed to act younger than their age, nor to occupy a privileged place in the family is recommended for children with short stature. Psychologic help is indicated in severe cases of depression or maladjustment.

2. PSYCHOSOCIAL DWARFISM (FIGURE 6–12)

Children with psychosocial dwarfism present with poor growth, a *pot-bellied* and immature appearance. They often display bizarre eating and drinking habits. Parents may report that the affected child begs for food from neighbors, forages in garbage cans, and drinks from toilet bowls. As a rule, this tragic condition occurs in only one of several children in a family. Careful questioning and observation reveal a disordered family structure in which the child is either ignored or severely disciplined. Caloric deprivation or physical battering may or may not be a feature of the history. These children have functional hypopituitarism. Testing often reveals GH deficiency at first, but after the child is removed from the home, GH function quickly returns to normal. Diagnosis rests on improvement in behavior or catch-up growth in the hospital or in a foster home. Separation from the family is therapeutic, but the prognosis is guarded. Family psychotherapy may be beneficial, but long-term follow-up is lacking.

Growth disorder due to abnormal parent–child interaction in a younger infant is *maternal deprivation* no matter which parent is most closely associated with the condition. Caloric deprivation due to parental neglect may be of greater significance in this younger age group. Even in the absence of nutritional restriction or full-blown psychosocial dwarfism, constant negative interactions within a family may inhibit the growth of a child.

It is essential to consider family dynamics in the evaluation of a child with poor growth. It is not appropriate to recommend GH therapy for emotional disorders.

3. HYPOTHYROIDISM

Thyroid hormone deficiency decreases postnatal growth rate and skeletal development. Congenital hypothyroidism leads to severe developmental delay unless treatment is rapidly provided after birth. Screening programs for the diagnosis of congenital hypothyroidism have been instituted all over the world. Early treatment following diagnosis in the neonatal period markedly reduces growth failure and has virtually eliminated developmental abnormalities caused by this disorder. Early treatment of congenital hypothyroidism results in normal growth. Acquired hypothyroidism in older children (eg, due to lymphocytic thyroiditis) may lead to growth failure. Characteristics of hypothyroidism are decreased growth rate and short stature, retarded bone age, and an increased US-LS ratio for chronologic age due to poor growth of the extremities. Patients are apathetic and sluggish and have constipation, bradycardia, coarsening of features and loss of hair, hoarseness, and delayed pubertal development, if the condition is untreated. Intelligence is unaffected in late-onset hypothyroidism, but the apathy and lethargy may make it seem otherwise. Although weight gain is possible with hypothyroidism, in contrast to common wisdom, it is not extreme.

The diagnosis of congenital hypothyroidism is usually made on the basis of neonatal screening studies. In this standard procedure, currently in use throughout the world, a sample of blood is taken from the heel or from the umbilical cord at birth and analyzed for total T_4 or TSH. A low total T_4 or free T_4 for age or an elevated TSH is usually indicative of congenital hypothyroidism; actual values differ by state and laboratory. A low total T_4 alone may be associated with low circulating thyroxine-binding globulin (TBG), but the significantly elevated TSH is diagnostic of primary hypothyroidism. The diagnosis may be accompanied by radiologic
FIGURE 6–12   Photograph and growth chart of a 9½-year-old boy with psychosocial dwarfism. He had a long history of poor growth (<3 cm/y). The social history revealed that he was given less attention and punished more frequently than his seven siblings. He ate from garbage cans and begged for food, though he was not apparently deprived of food at home. When the photograph was taken, he was 99 cm tall (–7 SD) and weighed 14.7 kg (–3 SD). His bone age was 5 years, with growth arrest lines visible. Serum thyroxine was 7.8 µg/dL. Peak serum GH varied from nondetectable to 8 ng/mL on different provocative tests between age 6 years and 8½ years. He was placed in a hospital chronic care facility (arrow) for a 6-month period and grew 9 cm, which projects to a yearly growth velocity of 18 cm. On repeat testing, the peak serum GH was 28 ng/mL.

evidence of retarded bone age or epiphyseal dysgenesis in severe congenital hypothyroidism.

In older children, serum TSH is the most reliable diagnostic test. Elevated TSH with decreased free T_4 may eliminate the potential confusion resulting from the use of total T_4, which may vary with the level of TBG or other thyroxine-binding proteins. A positive test for serum thyroglobulin antibodies or thyroperoxidase antibodies would lead to the diagnosis of autoimmune thyroid disease (Hashimoto thyroiditis) as an explanation for the development of hypothyroidism (see Chapter 7). If both FT_4 and TSH are low, the possibility of central hypothyroidism (pituitary or hypothalamic insufficiency) must be considered (this would not be revealed in a newborn screening programs that use primarily TSH screening). This should lead to a search for other hypothalamic-pituitary endocrine deficiencies such as GH deficiency and CNS disease (see Chapter 4).

Treatment is accomplished by thyroxine replacement. The dose varies from a range of 10 to 15 µg/kg in infancy to 2 to 3 µg/kg

in older children and teenagers. Suppression of TSH to normal values for age is a useful method for assessing the adequacy of replacement in acquired primary hypothyroidism. However, there are additional considerations in treatment of neonates as suppression of TSH is not appropriate in all affected newborns, and consultation with a pediatric endocrinologist is essential in this age group to ensure optimal dosing and adequate CNS development.

4. CUSHING SYNDROME

Excess glucocorticoids (either exogenous or endogenous) lead to decreased growth before obesity and other signs of Cushing syndrome develop. The underlying disease may be bilateral adrenal hyperplasia due to abnormal ACTH-cortisol regulation in Cushing disease, autonomous adrenal adenomas, or adrenal carcinoma. The appropriate diagnosis may be missed if urinary cortisol and 17-hydroxycorticosteroid determinations are not interpreted on the

basis of the child's body size or if inappropriate doses of dexamethasone are used for suppressive testing (appropriate doses are 20 μg/kg/d for the low-dose and 80 μg/kg/d for the high-dose dexamethasone suppression test) (see Chapter 9). Furthermore, daily variations in cortisol production necessitate several urinary or plasma cortisol determinations before Cushing disease can be appropriately diagnosed or ruled out. The high-dose dexamethasone test was positive in 68% of a recent series of children with Cushing disease. The corticotropin-releasing hormone test was positive in 80% of affected patients, whereas MRI of the pituitary was positive in only 52%. Inferior petrosal sampling (see Chapters 4 and 9) was 100% accurate in the diagnosis of Cushing disease, although technically difficult in children. The development of salivary cortisol assays makes the sampling of early morning salivary cortisol following a midnight dexamethasone dose an easier method to diagnose Cushing disease in children. Transsphenoidal microadenomectomy is the treatment of choice for Cushing disease.

Exogenous glucocorticoids used to treat asthma or even overzealous use of topical corticosteroid ointments or creams may suppress growth. These iatrogenic causes of Cushing syndrome, if resolved early, may allow catch-up growth and so may not affect adult height. Thus, an accurate history of prior medications is important in diagnosis. Treatment of the underlying disorder (eg, transsphenoidal microadenomectomy for Cushing disease) will restore growth rate to normal (catch-up growth may occur initially) if epiphyseal fusion has not occurred, but adult height will depend on the length of the period of growth suppression.

5. PSEUDOHYPOPARATHYROIDISM

Pseudohypoparathyroidism type 1A (OMIM #103580) is a rare disorder consisting of a characteristic phenotype and biochemical signs of hypoparathyroidism (low serum calcium and high serum phosphate) in its classic form. Phosphate is elevated in states of deficient parathyroid hormone (PTH) action, compared to vitamin D deficiency where phosphate levels are decreased while PTH is elevated. Circulating PTH levels are elevated in pseudohypoparathyroidism, but target tissues fail to respond to exogenous PTH administration. Children with classic pseudohypoparathyroidism are short and overweight, with characteristic round facies and short fourth and fifth metacarpals. This constellation of physical findings is called Albright hereditary osteodystrophy, which may be expressed separately from the biochemical disorders (see later). Developmental delay is common. The condition is due to heterozygous loss of function mutations in the alpha subunit of the G_s protein transducer (*GNAS1* gene). When imprinted paternally, this results in a defect in the G-protein that couples PTH receptors to adenylyl cyclase due to inheritance of the defective maternal allele. Thus, patients with pseudohypoparathyroidism type 1A have a blunted rise of urinary cAMP in response to administration of PTH. Remarkably, a defect occurs in the same regulatory protein system affected in McCune-Albright syndrome, in which hyperactive endocrine events result (see Chapters 1 and 8). A rarer variant of this disorder (pseudohypoparathyroidism type 1B; OMIM #603233) appears to be due to mutations in noncoding regions of the *GNAS1* gene. Treatment with high-dose vitamin D or

1,25-dihydroxyvitamin D (calcitriol) and exogenous calcium as well as phosphate-binding agents (if needed) will help correct the biochemical defects and control hypocalcemic seizures in patients with pseudohypoparathyroidism.

Two remarkable cousins are reported with pseudohypoparathyroidism and premature Leydig cell maturation, both due to abnormalities in the same G protein. The defective protein was shown to be inactive at normal body temperature, leading to defective PTH activity at the level of the kidney and bone. However, it was hyperactive at the cooler temperatures in the scrotum, leading to ligand-independent activation of Leydig cell function.

Children with the phenotype of Albright hereditary osteodystrophy but with normal circulating levels of calcium, phosphate, and PTH have pseudopseudohypoparathyroidism (OMIM #612463). They require no calcium or vitamin D therapy (see Chapter 8).

6. DISORDERS OF VITAMIN D METABOLISM

Short stature and poor growth are features of rickets in its obvious or more subtle forms. The cause may be vitamin D deficiency due to inadequate oral intake, fat malabsorption, inadequate sunlight exposure, anticonvulsant therapy, and/or renal or hepatic disease. Classic findings of vitamin D-deficient rickets include bowing of the legs, chest deformities (rachitic rosary), and characteristic radiographic findings of the extremities associated with decreased serum calcium and phosphate levels and elevated serum alkaline phosphatase levels. There are two forms of hereditary vitamin D-dependent rickets. Autosomal recessive type 1 hypophosphatemic rickets (OMIM #241520) involves a renal 25 OH vitamin D 1-hydroxylase deficiency, and type 2 (OMIM #613312) involves an absent or defective vitamin D receptor. However, the most common type of rickets in the United States is X-linked hypophosphatemic rickets (OMIM #307800), a dominant genetic disorder affecting renal reabsorption of phosphate. It is associated with short stature, severe and progressive bowing of the legs (but no changes in the wrists or chest), normal or slightly elevated serum calcium, very low serum phosphate, and urinary phosphate wasting. Short stature is linked with rickets in other renal disorders associated with renal phosphate wasting. Examples include Fanconi syndrome (including cystinosis and other inborn errors of metabolism) and RTA.

When treatment is effective in these disorders (eg, vitamin D for vitamin D deficiency or alkali therapy for appropriate types of RTA), growth rates will improve. Replacement of vitamin D and phosphate is appropriate therapy for vitamin D-resistant rickets. It improves the bowing of the legs and leads to improved growth, although there is a risk of nephrocalcinosis with vitamin D treatment. This necessitates annual renal ultrasound examinations when patients are receiving vitamin D therapy.

In the Williams-Bureun syndrome of elfin facies, supravalvular aortic stenosis, and mental retardation with gregarious personality, patients have SGA and greatly reduced height in childhood and as adults; this disorder may include infantile hypercalcemia but is no longer considered a disorder of vitamin D metabolism because a genetic defect in the *elastin* gene at 7q11.23 occurs in most affected patients (#194050).

7. DIABETES MELLITUS

Growth in type 1 diabetes mellitus depends on the efficacy of therapy. Well-controlled diabetes mellitus is compatible with normal growth, whereas poorly controlled diabetes often causes slow growth. Liver and spleen enlargement in a poorly controlled, short, diabetic child is known as Mauriac syndrome, rarely seen now owing to improved diabetes care. Another factor that may decrease growth rate in children with type 1 diabetes mellitus is the increased incidence of Hashimoto thyroiditis in this population. Yearly thyroid function screening is advisable, especially as the peripubertal period approaches. GH concentrations are higher in children with diabetes, and this factor may play a role in the development of diabetic complications. IGF-I concentrations tend to be normal or low, depending on glucose control, but judging from the elevated GH noted earlier, the stimulation of IGF-I production by GH appears to be partially blocked in these children. Celiac disease may occur in 10% of children with type 1 diabetes and can itself lead to growth failure.

8. DIABETES INSIPIDUS

Polyuria and polydipsia due to inadequate vasopressin (central or neurogenic diabetes insipidus) or inability of the kidney to respond to vasopressin (nephrogenic diabetes insipidus) lead to poor caloric intake and decreased growth. With appropriate treatment (see Chapter 5), the growth rate should return to normal. Acquired neurogenic or central diabetes insipidus may indicate the development of a hypothalamic-pituitary tumor, and growth failure may be due to associated GH deficiency.

DIAGNOSIS OF SHORT STATURE (TABLES 6–3, 6–4, AND 6–5)

Evaluation of Short Stature

An initial decision must determine whether a child is pathologically short or simply distressed because height is not as close to the 50th percentile as desired by the patient or the parents. Performing unnecessary tests is expensive and may be a source of

TABLE 6–3 Basic diagnosis of short stature.

Medical History
Birth weight and gestational age
Prenatal substance abuse
Birth trauma or complications
Family heights
Age of puberty or menarche in family
Family history of or symptoms of chronic diseases
Dietary history
Physical Examination
Measured and charted height
Measured and charted weight and BMI
Signs of syndromes
Midline defects
Neurological examination
Findings of chronic disease

TABLE 6–4 The laboratory evaluation of short stature.

Test	Rationale
CBC	*Anemia*: nutritional, chronic disease, malignancy *Leukocytosis*: inflammation, infection *Leukopenia*: bone marrow failure syndromes *Thrombocytopenia*: malignancy, infection
ESR, CRP	Inflammation of infection, inflammatory diseases, malignancy
Chemistry panel (electrolytes, liver enzymes, BUN)	Signs of acute or chronic hepatic, renal, adrenal dysfunction; hydration and acid-base status
Carotene, folate, tissue transglutaminase antibody, or reflex celiac panel	Assess malabsorption; detect celiac disease
Urinalysis	Signs of renal dysfunction, hydration; renal tubular acidosis
Karyotype, candidate gene analysis, SNP analysis using microarrays on DNA chips, array-comparative genomic hybridization (array-CGH), or other genomic techniques	Evaluate for genetic syndromes
Cranial MRI imaging	Assesses hypothalamic-pituitary tumors (craniopharyngioma, glioma, germinoma) or congenital midline defects
Bone age	Determine physiologic maturation, and evaluate height potential
IGF-I, IGF BP3	Reflects growth hormone status or nutrition
Free thyroxine and TSH	Detects hypothyroidism
Prolactin	Elevated in hypothalamic dysfunction or destruction, suppressed in pituitary disease

Abbreviations: BUN, blood urea nitrogen; CBC, complete blood count; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IGF, insulin like growth factor-binding protein 3; MRI, magnetic resonance imaging; TSH, thyroid-stimulating hormone.

TABLE 6–5 Growth hormone testing.

Growth hormone testing is last and only performed if no other diagnosis is found
Never get basal serum GH unless you suspect gigantism!
Stimulated tests:
L-Dopa
Clonidine
Arginine
Glucagon
Insulin-induced hypoglycemia (very dangerous)
GHRH
Growth hormone–releasing peptides (GRP)

long-term concern to the parents—a concern that could be avoided by appropriate reassurance. Alternatively, missing a diagnosis of pathologic poor growth may cause the patient to lose inches of final height or may allow progression of serious disease.

If a patient's stature, growth rate, or height adjusted for midparental height is sufficiently decreased to warrant evaluation, an orderly approach to diagnosis will eliminate unnecessary laboratory testing. The medical history will provide invaluable information as to the intrauterine course and toxin exposure and the possibility of birth trauma as well as an indication of other acute or chronic diseases and dietary intake. Birthweight and gestational age determine whether the child is SGA or AGA. The evaluation for dietary deficiencies and for symptoms of any chronic disease is important since almost any systemic disease or nutritional compromise can decrease growth rate (see Table 6–1). Review of past growth charts is important, but in this modern era, children often change doctors frequently, and these data may not be available. Asking whether the child has changed clothing sizes or shoe sizes is useful in the absence of any other data that may allow determination of growth rate. Heights of parents and age of puberty of parents are recorded although usually only a mother will recall her age of menarche while the father will not likely remember anything about his pubertal development (unless the father continued to grow after he left high school which might indicate constitutional delay in puberty). The height of siblings and specifically their percentile of height and whether they entered puberty at an appropriate time is important. The presence of chronic disease in the family is also noted in the history. Evaluation of psychosocial factors affecting the family and the relationship of parents and child can be carried out during the history-taking encounter. Often the diagnosis can be made at this point.

It goes without saying that accurate measurement of growth is essential. The physical examination requires determination of height as described earlier, and comparison is carried out with any previous data available. Measurement of weight and the calculation of BMI are performed so that neither obesity nor malnutrition is missed. If past heights are not available, a history of lack of change in clothing and shoe sizes or failure to lengthen skirts or pants may reflect poor growth. Questions about how the child's stature compares with that of his or her peers and whether the child's height has always had the same relationship to that of classmates is useful. One of the most important features of the evaluation process is to determine height velocity and compare the child's growth rate with the normal growth rate for age. Adjustment for midparental height is calculated and nutritional status determined. Arm span, head circumference, and US-LS ratio are measured. Physical examination is directed to uncover signs of chronic disease, CNS condition or a midline defect of the CNS that may be related to hypothalamic pituitary dysfunction. Physical stigmas of syndromes or systemic diseases are evaluated. Neurologic examination is essential.

Any clues to a diagnosis in the history or physical examination are pursued. However, if no historical or physical features lead to an etiology, laboratory examinations are performed (see Table 6–4). A list of chronic diseases causing short stature is presented in Table 6–1. Complete blood count and serum chemistry screening with electrolyte measurements may reveal anemia, abnormalities of hepatic or renal disease, glucose intolerance, acidosis, calcium disorder, or other electrolyte disturbances. Age-adjusted values must be used (eg, the normal ranges of serum alkaline phosphatase and phosphorus values are higher in children than in adults). An elevated sedimentation rate, low serum carotene, or a positive antinuclear, or tissue transglutaminase antibody determination (if IgA determination first eliminates the possibility of IgA deficiency providing a false negative test) may indicate connective tissue disease, Crohn's disease, celiac disease, or malabsorption syndrome. Serum TSH and free T_4 are important measurements to exclude existing thyroid disease. Urinalysis is done, with attention to specific gravity (to rule out diabetes insipidus) and ability to acidify urine (to evaluate possible RTA). Skeletal age evaluation does not alone provide a diagnosis; however, if the study shows delayed bone age, the possibility of constitutional delay in growth, hypothyroidism, or GH deficiency must be considered. The tests used for the diagnosis of GH deficiency are detailed earlier (see Table 6–5). If serum IGF-I is normal for age, classic GH deficiency or malnutrition is unlikely; if serum IGF-I is low, it must be considered in relation to skeletal age, nutritional status, and general health status before interpretation of the value can be made. Since IGF-I values are low under 2 or 3 years of age, the simultaneous measurement of IGFBP-3 is useful in infants. If either or both IGF-I and IGFBP-3 are low, the diagnosis may be GH deficiency if poor nutrition is ruled out. If GH deficiency or impairment is found or if there is another hypothalamic-pituitary defect, an MRI is indicated with particular attention to the hypothalamic-pituitary area to rule out a congenital defect or neoplasm in the area. The appearance of an ectopic location of the posterior pituitary on MRI is relatively frequent in congenital GH deficiency, as is a decreased pituitary volume or apparent interruption of the pituitary stalk. Serum gonadotropin and sex steroid determinations are performed in pediatric assays if puberty is delayed (see Chapter 15). Serum prolactin may be elevated in the presence of a hypothalamic disorder.

Celiac disease is quite common as a cause of gastrointestinal distress and/or short stature. Serum IgA levels and tissue transglutaminase antibody measurements are indicated in the evaluation of growth disorders. A karyotype is obtained in any short girl without another diagnosis to rule out Turner syndrome, especially if puberty is delayed or gonadotropins are elevated. If Turner syndrome is diagnosed, evaluation of thyroid function and determination of thyroid antibodies is also important.

Elevated urinary free cortisol (normal: <60 μg/m^2/24 h [<18.7 μmol/m^2/24 h]), elevated late night salivary cortisol, or abnormal dexamethasone suppression testing signifies Cushing syndrome.

If no diagnosis is apparent after all of the above have been considered and evaluated, more detailed procedures, such as provocative testing for GH deficiency, are indicated. It must be emphasized that a long and expensive evaluation is not appropriate until psychologic or nutritional factors are ruled out. Likewise, if a healthy-appearing child presents with borderline short stature, normal growth rate, and short familial stature, a period of observation may be more appropriate than laboratory tests.

TALL STATURE DUE TO NONENDOCRINE CAUSES

1. CONSTITUTIONAL TALL STATURE

A subject who has been taller than his or her peers through most of childhood is growing at a velocity within the normal range with a moderately advanced bone age, and has no signs of the disorders listed later, may be considered to be constitutionally advanced. Predicted final height will usually be in the normal adult range for the family.

Obesity in an otherwise healthy child will often, especially in the presence of a melanocortin 4 receptor (MC4R) mutation, lead to moderate advancement of bone age, slightly increased growth rate, and tall stature in childhood. Age of puberty will begin in the early range of normal, and adult stature will conform to genetic influences. Thus, an obese child without endocrine disease should be tall; short stature and obesity are worrisome.

2. FAMILIAL/GENETIC TALL STATURE

Children with exceptionally tall parents have a genetic tendency to reach a height above the normal range. The child will be tall for age and will grow at a normal to high normal rate. Bone age will be close to chronologic age, leading to a tall height prediction. Occasionally, children will be concerned about being too tall as adults. These worries are more common in girls and will often be of greater concern to the parents than to the patient. Adult height was limited in the past by promoting early epiphyseal closure with estrogen in girls or testosterone in boys, but such therapy is no longer considered appropriate. Testosterone therapy decreases HDL cholesterol levels. Acne fulminans may be caused by testosterone therapy and progression may occur, even after therapy has been withdrawn. Estrogen carries the theoretical risk of thrombosis, ovarian cysts, and galactorrhea, and recent report of decreased fertility. High-dose estrogen therapy is estimated to decrease predicted final height by as much as 4.5 to 7 cm but only if started 3 to 4 years before epiphyseal fusion. Such height-limiting therapy is extremely rare in the present era although, recently, long-acting somatostatin agonists have been used in an attempt to limit height in selected subjects. Counseling and reassurance are more appropriate.

3. SYNDROMES OF TALL STATURE

Cerebral Gigantism

The sporadic syndrome of rapid growth in infancy, prominent forehead, high-arched palate, sharp chin, and hypertelorism [Sotos syndrome (OMIM #117550)] is caused by mutation in the *nuclear receptor–binding SET domain protein 1* (*NSD1*) gene and is not associated with GH excess. Mentation is usually impaired. The growth rate decreases to normal in later childhood, but stature remains tall.

Marfan Syndrome

Marfan syndrome (OMIM #154700) is an autosomal dominant abnormality of connective tissue exhibiting variable penetrance.

The disorder is due to mutation of the *fibrillin 1* gene located on 15q21.1. This condition may be diagnosed by characteristic physical manifestations of tall stature, long thin fingers (arachnodactyly), hyperextension of joints, and superior lens subluxation. Pectus excavatum and scoliosis may be noted. Furthermore, aortic or mitral regurgitation or aortic root dilation may be present, and aortic dissection or rupture may ultimately occur. In patients with this syndrome, arm span exceeds height, and the US-LS ratio is quite low owing to long legs. Aortic root ultrasound and slit lamp ophthalmologic examinations are indicated.

Homocystinuria

Patients with homocystinuria (OMIM #236200) have an autosomal recessive deficiency of cystathionine beta-synthase (gene locus 21q22.3) and phenotypes similar to those of patients with Marfan syndrome. Additional features of homocystinuria include developmental delay, increased incidence of seizures, osteoporosis, inferior lens dislocation, and increased urinary excretion of homocystine with increased plasma homocystine and methionine but low plasma cystine. Thromboembolic phenomena may precipitate a fatal complication. This disease is treated by restricting dietary methionine and, in responsive patients, administering pyridoxine.

Beckwith-Wiedemann Syndrome

Patients with Beckwith-Wiedemann syndrome (OMIM #130650) demonstrate macrosomia (birth weight >90th percentile) in 88% of cases, increased postnatal growth, omphalocele in 80%, macroglossia in 97%, and hypoglycemia due to the hyperinsulinism of pancreatic hyperplasia in 63%. Other reported features include fetal adrenocortical cytomegaly and large kidneys with medullary dysplasia. The majority of patients occur in a sporadic pattern due to a mutation at 11p15.5, but analysis of some pedigrees suggests the possibility of familial patterns. There is a risk of Wilms tumor, hepatoblastoma, adrenal carcinoma, and gonadoblastoma in this condition.

XYY Syndrome

Patients with one (47,XYY) or more (48,XYYY) extra Y chromosomes achieve greater than average adult heights. They have normal birth lengths but higher than normal growth rates. Excess GH secretion has not been documented (see Chapter 14).

Klinefelter Syndrome

Patients with Klinefelter syndrome (see Chapters 12 and 14) tend toward tall stature, but this is not a constant feature.

TALL STATURE DUE TO ENDOCRINE DISORDERS

1. PITUITARY GIGANTISM

Pituitary gigantism is caused by excess GH secretion before the age of epiphyseal fusion. The increased GH secretion may be due

to somatotroph-secreting tumors or constitutive activation of GH secretion as is sometimes found in the McCune-Albright syndrome. Alternatively, it may result from excess secretion of GHRH. Patients—besides growing excessively rapidly—have coarse features, large hands and feet with thick fingers and toes, and often frontal bossing and large jaws.

Although this condition is quite rare, the findings appear similar to those observed in the more frequently diagnosed acromegaly (which occurs with GH excess after epiphyseal fusion). Thus, glucose intolerance or frank diabetes mellitus, hypogonadism, and thyromegaly are predicted. Treatment is accomplished by surgery (the transsphenoidal approach is used if the tumor is small enough), radiation therapy, or by medical therapy with a somatostatin analog.

2. SEXUAL PRECOCITY

Early onset of estrogen or androgen secretion leads to abnormally increased height velocity. Because bone age is advanced, there is the paradox of the tall child who, because of early epiphyseal closure, is short as an adult. The conditions include complete and incomplete sexual precocity (including virilizing congenital adrenal hyperplasia) (see Chapter 14).

3. THYROTOXICOSIS

Excessive thyroid hormone, due to endogenous overproduction or overtreatment with exogenous thyroxine, leads to increased growth, advanced bone age, and, if occurring in early life, craniosynostosis. If the condition remains untreated, adult height will be reduced due to early epiphyseal closure.

4. INFANTS OF DIABETIC MOTHERS

Birth weight and size in infants of diabetic mothers are quite usually high, although severely affected, poorly controlled mothers with type 1 diabetes may have infants with IUGR due to placental vascular insufficiency. Severe hypoglycemia and hypocalcemia are evident in the affected infants soon after birth. The appearance and size of such infants is so striking that women have been diagnosed with gestational diabetes as a result of giving birth to large affected infants. By 10 years of age, infants of diabetic mothers have an increased prevalence of obesity as well as insulin resistance and all of the comorbidities of the condition.

The Thyroid Gland

David S. Cooper, MD and
Paul W. Ladenson, MD (Oxon)., MD

Ab	antibody		**rhTSH**	recombinant human TSH
ClO$_4^-$	perchlorate ion		**rT$_3$**	reverse triiodothyronine
DIT	diiodotyrosine		**RTH**	resistance to thyroid hormones
FNAB	fine-needle aspiration biopsy		**RXR**	retinoid X receptor
FSH	follicle-stimulating hormone		**SMRT**	silencing mediator for retinoic and thyroid hormone receptors
GRTH	generalized resistance to thyroid hormone		**T$_4$**	thyroxine
hCG	human chorionic gonadotropin		**T$_3$**	triiodothyronine
LH	luteinizing hormone		**TBG**	thyroxine-binding globulin
MCT	monocarboxylate transporter		**TBPA**	transthyretin or thyroxine-binding prealbumin
MIT	monoiodotyrosine		**TG**	thyroglobulin
NADPH	nicotinamide adenine dinucleotide phosphate		**TPO**	thyroid peroxidase
NCoR	nuclear receptor corepressor		**TR**	thyroid hormone receptor
NIS	sodium-iodide symporter		**TRH**	thyrotropin-releasing hormone
OATP1C1	organic anion transporting polypeptide		**TSH**	thyroid-stimulating hormone (thyrotropin)
PTU	propylthiouracil		**WHO**	World Health Organization
RAIU	radioactive iodine uptake			

The thyroid gland is the body's largest single organ specialized for endocrine hormone production. Its function is to secrete an appropriate amount of the thyroid hormones, primarily 3,5,3′,5′-l-tetraiodothyronine (thyroxine, T$_4$), and a lesser quantity of 3,5,3′-l-triiodothyronine (T$_3$), which arises mainly from the subsequent extrathyroidal deiodination of T$_4$. In target tissues, T$_3$ interacts with nuclear T$_3$ receptors that are, in turn, bound to special nucleotide sequences in the promoter regions of genes that are positively or negatively regulated by thyroid hormone. The thyroid hormones promote normal fetal and childhood growth and central nervous system development; regulate heart rate and myocardial contraction and relaxation; affect gastrointestinal motility and renal water clearance; and modulate the body's energy expenditure, heat generation, weight, and lipid metabolism. In addition, the thyroid contains parafollicular or C cells that produce calcitonin, a 32-amino-acid polypeptide that inhibits bone resorption, but has no apparent physiologic role in humans.

However, calcitonin is clinically important as a tumor marker produced by medullary thyroid cancers that arise from these cells (see Chapter 8).

EMBRYOLOGY, ANATOMY, AND HISTOLOGY

The thyroid gland originates in the embryo as a mesodermal invagination in the pharyngeal floor at the foramen cecum, from which it descends anterior to the trachea and bifurcates, forming two lateral lobes, each measuring approximately 4 cm in length, 2 cm in width, and 1 cm in thickness in adulthood. Ectopic thyroid tissue can be present anywhere along or beyond this thyroglossal duct, from the tongue base (lingual thyroid) to the mediastinum. The thyroglossal duct may also give rise to midline
FIGURE 7–1 Gross anatomy of the human thyroid gland (anterior view).

cysts lined with squamous epithelium, which can remain asymptomatic, or become infected or give rise to thyroid tumors. The caudal end of the thyroglossal duct forms the pyramidal lobe of the thyroid, which can become palpable in conditions causing diffuse thyroid inflammation or stimulation (Figure 7–1).

Because the posterior thyroid capsule is bound to the pretracheal fascia, the gland normally rises and falls with deglutition, facilitating its inspection and palpation. When the thyroid enlarges, posterior and downward growth of goiter can extend into the superior mediastinum (substernal goiter), whereas upward extension of the thyroid gland is limited by the attachment of the sternothyroid muscle to the thyroid cartilage. The thyroid gland also has clinically important anatomical relationships to the recurrent laryngeal nerves, which course behind the gland, and two pairs of parathyroid glands that usually lie behind the upper and middle portions of the thyroid lobes. The thyroid is also draped around the trachea and the posterior margins of its lobes abut the esophagus. All of these structures can be compressed by gland enlargement, invaded by thyroid malignancies, or injured in the course of thyroid surgery (Figure 7–2).

The thyroid gland has a rich blood supply (Figure 7–3), which can be increased in hyperthyroidism,[1] giving rise to an audible whooshing sound (bruit) or even a palpable vibration (thrill). Microscopically, thyrocytes form hollow spheres (follicles) that surround a central lumen containing an aggregation of iodinated thyroglobulin (TG) (colloid) that represents the gland's hormone stores (Figure 7–4).

---

[1]In this chapter, the term "hyperthyroidism," which strictly speaking refers only to thyroid hormone excess due to overproduction of thyroid hormone by the gland, is sometimes used interchangeably with "thyrotoxicosis," which indicates all states of thyroid hormone excess.

PHYSIOLOGY

STRUCTURE AND SYNTHESIS OF THYROID HORMONES

The thyroid hormones are iodinated thyronines, which consist of two tyrosine moieties joined by an ether linkage (Figure 7–5). The follicular cells of the thyroid gland are specialized in their ability to synthesize the large hormonal precursor protein TG, concentrate iodide intracellularly from the circulation, and express a receptor that binds thyroid-stimulating hormone (thyrotropin, TSH), which promotes thyrocytes' growth and biosynthetic functions.

IODINE METABOLISM

Iodine[2] is a key structural component of thyroid hormones. Consequently, it is an essential micronutrient consumed in food or water as iodide or iodate, which is converted to iodide in the stomach. The World Health Organization (WHO) recommends a daily dietary iodine intake of 150 μg for adults, 200 μg for pregnant and lactating women, and 90 μg for children. Because most iodide is excreted by the kidneys, urinary iodide excretion is an excellent index of dietary intake.

Over millennia, iodine has been leached from the soil in many mountainous and inland regions of the world. Consequently, according to WHO, dietary iodine deficiency, defined as a daily

---

[2]In this chapter, the words "iodine," referring to the uncharged element, and "iodide," referring to its negatively charged anion form, are used interchangeably.
FIGURE 7–2 Cross-section of the neck at the level of T$_1$, showing thyroid relationships. (Reproduced with permission from Lindner HH. *Clinical Anatomy*. New York: McGraw-Hill Education; 1989.)

iodine intake less than 100 μg/d, affects an estimated two billion people, which is about one-third of the world's population. When iodide intake is less than 50 μg/d, a normal-sized thyroid cannot sustain adequate hormone production, with resulting gland enlargement (goiter) and, ultimately, hypothyroidism. The consequences of endemic dietary iodine deficiency are especially devastating for the developing fetus and children, who require thyroid hormone for normal neurologic development and growth. In the North American diet, iodine is principally derived from iodized

salt, iodate preservatives in baked goods, dairy products containing traces of iodophore antibacterial agents used in milk collection, food coloring, and seafood.

Thyrocytes abundantly express the sodium-iodide symporter (Na-I$^-$ symporter; NIS), which spans the cells' basal membranes and actively transports iodide from the blood. The thyroid gland concentrates and uses only a fraction of the iodide supplied to it for hormone synthesis, and the remainder returns to the extracellular fluid pool. Consequently, the normal fractional uptake of

iodide, which can be quantified with a radioactive iodine tracer, is approximately 10% to 30% after 24 hours. Because of this active concentrating mechanism and the subsequent organification of intracellular iodide, the intrathyroidal pool of iodine, 8 to 10 mg in the form of stored thyroid hormones and iodinated tyrosines, provides a buffer in the event of temporary dietary iodine deficiency.

THYROID HORMONE SYNTHESIS AND SECRETION

Synthesis of T_4 and T_3 by the thyroid gland involves six major steps: (1) active transport of iodide across the basement membrane into the thyroid cell (trapping); (2) oxidation of iodide and iodination of tyrosyl residues in TG (organification); (3) linking pairs of iodotyrosine molecules within TG to form the iodothyronines T_3 and T_4 (coupling); (4) pinocytosis and then proteolysis of TG with release of free iodothyronines and iodotyrosines into the circulation; (5) deiodination of iodotyrosines within the thyroid cell, with conservation and reuse of the liberated iodide; and (6) intrathyroidal 5′-deiodination of T_4 to T_3.

Thyroid hormone synthesis requires that NIS, TG, and the enzyme thyroid peroxidase (TPO) all be present, functional, and uninhibited. This process is summarized in Figures 7–6 and 7–7.

Thyroglobulin

TG is a large glycoprotein molecule (MW 660,000 kD), composed of two subunits, each containing 5496 amino acids. TG includes approximately 140 tyrosyl residues, but only four tyrosyl sites in each molecule are sterically oriented for effective hormonogenesis. The iodine content of TG can vary from 0.1% to 1% by weight. In TG containing 0.5% iodine, for example, there are approximately three molecules of T_4 and one molecule of T_3.
FIGURE 7–6 The iodide transporter in the thyroid cell. The pink solid circle represents the Na^+/I^- symporter actively transporting I^- into the cell; the blue solid circle represents Na^+-K^+ ATPase supplying the ion gradient which drives the reaction. I^- is transported across the apical membrane by pendrin. Hormone synthesis takes place in the colloid at the colloid–apical membrane, catalyzed by thyroperoxidase (TPO).

The *TG* gene, which resides on the long arm of chromosome 8, contains approximately 8500 nucleotides, which encode the prethyroglobulin protein monomer, including a 19-amino acid signal peptide. TSH regulates expression of the *TG* gene. After TG mRNA is translated in the rough endoplasmic reticulum (RER), the protein is glycosylated during transport through the Golgi apparatus (see Figure 7–7), where TG dimers are incorporated into exocytic vesicles. These vesicles then fuse with the cell's apical basement membrane, from which they are released into the follicular lumen. There, at the apical–colloid border, tyrosine residues in TG are iodinated.

Iodide Transport

Iodide (I^-) is transported across thyrocytes' basal membrane by the NIS. Membrane-bound NIS, which derives its energy from a Na^+-K^+ ATPase, allows the human thyroid gland to maintain a concentration of free iodide 30 to 40 times higher than that in plasma. NIS action is stimulated physiologically by TSH and pathophysiologically by the TSH receptor–stimulating antibody (Ab) of Graves disease. Salivary, gastric, and breast tissues also express NIS and concentrate iodide to a lesser extent than the thyroid, but these other tissues do not organify or store iodide, and their NIS activities are not stimulated by TSH. However, these tissues may concentrate enough iodine to be visualized on radioiodine scans and irradiated with high-dose 131-I therapy, causing radiation sialadenitis and gastritis.

Large amounts of iodide suppress both NIS activity and *NIS* gene expression, representing mechanisms of iodine autoregulation (see later). The perchlorate ion (ClO_4^-) competes with iodide for NIS; perchlorate has been used to treat hyperthyroidism and
FIGURE 7–7 Processes of synthesis and iodination of thyroglobulin (left) and its reabsorption and digestion (right). These events occur in the same cell. (Reproduced with permission from Junqueira LC, Carneiro J, Kelley R. *Basic Histology*, 7th ed. New York: McGraw-Hill Education; 1992.)

has the potential to be an environmental inhibitor of thyroid function. NIS can also concentrate pertechnetate (TcO_4^-) into thyroid cells, facilitating use of the radionuclide sodium pertechnetate ($^{99m}TcO_4^-$) for visualization of the thyroid gland and quantification of its trapping activity.

At the thyrocyte's apical border, a second iodide transport protein, pendrin, transports iodide to the membrane–colloid interface, where it becomes a substrate for thyroid hormonogenesis (see Figures 7–6 and 7–7). Mutations in the *pendrin* (PDS or SLC26A4) gene impairing its function cause a syndrome of goiter and hearing loss acquired in infancy or early childhood (Pendred syndrome).

Thyroid Peroxidase

TPO, a membrane-bound glycoprotein (MW 102 kD) containing a heme moiety, catalyzes both iodide oxidation and covalent linkage of iodine to the tyrosine residues of TG. *TPO* gene expression is stimulated by TSH. After TPO is synthesized in the RER, it is inserted into the RER's cisternal membranes, from which it is transferred to the apical cell surface through Golgi elements and exocytic vesicles. Here, at the cell–colloid interface, TPO facilitates both iodination and coupling of the tyrosine residues within TG.

Iodination of Thyroglobulin

Within the thyroid cell, at the apical–colloid interface, iodide is rapidly oxidized by locally produced hydrogen peroxide in a reaction catalyzed by TPO; the resulting active iodide intermediate is bound to tyrosyl residues in TG. The required hydrogen peroxide is probably generated by a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in the presence of calcium cations, a process that is also stimulated by TSH.

Coupling of Iodotyrosyl Residues in Thyroglobulin

The coupling of iodotyrosyl residues in TG is also catalyzed by TPO. This is believed to be an intramolecular process involving oxidation of two iodotyrosyl residues brought into proximity by the tertiary and quaternary structures of TG, their linkage as a quinol ether intermediate, and splitting of the quinol ether to form an iodothyronine (Figure 7–8). Within the TG molecule, two molecules of diiodotyrosine (DIT) couple to form T_4, and monoiodotyrosine (MIT) and DIT molecules couple to form T_3.

The thiocarbamide drugs, including methimazole, carbimazole, and propylthiouracil (PTU), are competitive inhibitors of TPO. Their resulting ability to block thyroid hormone synthesis (Figure 7–9) makes them useful in treatment of hyperthyroidism.

Proteolysis of Thyroglobulin and Thyroid Hormone Secretion

The processes of TG proteolysis and secretion in thyroid hormonogenesis are illustrated in Figure 7–7. At the thyrocyte's apical
FIGURE 7–8 Hypothetical coupling scheme for intramolecular formation of T_4 within the thyroglobulin molecule. The major hormonogenic site at tyrosyl residue 5 is indicated. (Reproduced with permission from Braverman LE, Utiger RD. *Werner and Ingbar's The Thyroid*, 7th ed. Philadelphia: Lippincott Williams & Wilkins; 1996.)

membrane, colloid is engulfed in vesicles by pinocytosis and absorbed into the cell. Lysosomes containing proteolytic enzymes then fuse with the colloid vesicle. This releases T_4 and T_3, as well as inactive iodotyrosines, peptides, and individual amino acids. The biologically active thyroid hormones T_4 and T_3 enter the circulation; DIT and MIT are deiodinated and their iodide conserved. Thyroid hormone secretion is stimulated by TSH and inhibited by excess iodide (see later) and lithium. Intact TG is also normally released from thyroid cell and circulates in blood.
FIGURE 7–9 Thiocarbamide inhibitors of thyroidal iodide organification.

The serum TG concentration is markedly increased in a number of thyroid conditions, including thyroiditis, nodular goiter, and Graves disease. Because TG is also synthesized by most malignancies arising from thyroid epithelium, such as papillary and follicular thyroid cancers, it is a useful circulating tumor marker.

Intrathyroidal Deiodination

MIT and DIT formed during the synthesis of thyroid hormone are deiodinated by intrathyroidal deiodinase, an NADPH-dependent flavoprotein found in mitochondria and microsomes that acts on the iodotyrosines MIT and DIT, but not on T_3 and T_4. Most of the iodide released is reused for hormone synthesis, and only a small amount normally leaks out of the thyroid gland (Figure 7–10).

The 5′-deiodinase that converts T_4 to T_3 in peripheral tissues is also found in the thyroid gland. When there is iodide deficiency and in various hyperthyroid states, the activity of this enzyme increases the amount of T_3 secreted by the gland, increasing the metabolic efficiency of hormone synthesis.

ABNORMALITIES IN THYROID HORMONE SYNTHESIS AND RELEASE

Dietary Iodine Deficiency and Inherited Defects

A very low-iodine diet and inherited defects in genes encoding the proteins required for thyroid hormone biosynthesis (dyshormonogenesis) can both result in insufficient hormone production. In response to limited intrathyroidal iodine content or hormone production, the gland increases the ratios of MIT-to-DIT within TG as well as the proportion of secreted T_3 relative to T_4. The hypothalamic-pituitary-thyroid axis also responds to thyroid hormone deficiency by increasing TSH secretion. Consequently, affected individuals typically present with thyroid gland enlargement (goiter), which may be sufficient to compensate for inefficient thyroid hormone production; but if not, they develop hypothyroidism. Severely affected neonates and infants can suffer the irreversible effects of thyroid hormone deficiency on
FIGURE 7–10 Iodine metabolism. The values indicated are representative of those that might be found in a healthy subject ingesting 500 μg of iodine a day. The actual iodine intake varies considerably among different individuals.

development that result in cretinism. Specific inherited disorders are described in more detail in the section Nontoxic Goiter, later.

Effects of Iodine Excess on Hormone Biosynthesis

Although iodide is an essential substrate for thyroid hormone production, excess iodide actually inhibits three steps in thyroid hormone production: iodide trapping, TG iodination (the Wolff-Chaikoff effect), and thyroid hormone release from the gland. These inhibitory actions are transient, and the normal thyroid gland *escapes* after 10 to 14 days from these effects of excess iodide. These autoregulatory effects of iodide insulate physiologic thyroid function from short-term fluctuations in iodine intake.

These actions of excess iodide also have important clinical implications, sometimes causing iodine-induced thyroid dysfunction. If the thyroid is affected by autoimmune thyroiditis or certain inherited forms of dyshormonogenesis, it may be incapable of escaping from sustained iodide-induced inhibition of gland function, and hypothyroidism can develop. Conversely, an iodide load can induce hyperthyroidism (Jod-Basedow effect[3]) in some patients with multinodular goiter, latent Graves disease, and rarely in individuals with thyroid glands that appear otherwise normal. The inhibitory effects of pharmacological iodide doses make iodide a useful treatment for short-term control of hyperthyroidism, such as before surgery. Iodide can also prevent thyroid gland exposure to radiation injury when populations are exposed to environmental radioiodine, such as after nuclear power plant accidents.

THYROID HORMONE TRANSPORT

Both thyroid hormones circulate in blood bound to plasma proteins; only 0.04% of T_4 and 0.4% of T_3 are unbound or free, and consequently, available for entry and action in target tissues (Figure 7–11). There are three major thyroid hormone transport proteins: thyroxine-binding globulin (TBG); transthyretin, formerly called thyroxine-binding prealbumin (TBPA), and albumin (Figure 7–12). The plasma protein binding permits blood delivery of the iodothyronines, which are otherwise poorly soluble in water. It also creates a large circulating thyroid hormone pool with a stable 7-day plasma half-life and ensures the homogeneous distribution of thyroid hormones in target tissues.

Thyroxine-Binding Globulin

TBG is a liver-derived glycoprotein member of the SERPIN family of serine antiproteases composed of a single 54-kD polypeptide chain, to which are attached four carbohydrate chains normally containing approximately 10 sialic acid residues. Each TBG molecule has a single binding site for T_4 or T_3. The serum concentration of TBG is 15 to 30 μg/mL (280-560 nmol/L), and its high-binding affinity for T_4 and T_3 allows it to carry about 70% of circulating thyroid hormones.

[3]Jod is German for iodine; Carl Adolph von Basedow was one of the first physicians to describe hyperthyroidism.
FIGURE 7–11 Representation of free T_4 (and free T_3) as the biologically active hormones at the level of the pituitary and the peripheral tissues. Most of the thyroid hormones circulating in plasma are protein-bound and have no biologic activity. This pool of bound hormone is in equilibrium with the free hormone pool. (Reproduced with permission from DeGroot LJ, Stanbury JB. *The Thyroid and Its Diseases*, 4th ed. Philadelphia: Elsevier; 1975.)

TBG and its binding of the thyroid hormones can be altered by congenital TBG derangements, certain physiologic and pathophysiologic circumstances, and several drugs. TBG deficiency occurs with a frequency of 1:5000 live births, with a number of variants described in several ethnic and racial groups. It is an X-linked recessive trait that, consequently, is much more commonly expressed in males. Despite low circulating total T_4 and T_3 levels in affected individuals, free-hormone levels are normal, and these patients remain euthyroid. Congenital TBG deficiency is often associated with congenital corticosteroid-binding globulin deficiency (see Chapter 9). Conversely, congenital TBG excess, which is rare, is characterized by elevated total T_4 and T_3 concentrations in blood, but normal free-hormone levels and a euthyroid clinical state. Pregnancy, estrogen-secreting tumors, and estrogen therapy all increase the sialic acid content of the TBG molecule, resulting in decreased metabolic clearance and elevated serum TBG levels. TBG levels can decrease with accelerated clearance in nephrotic syndrome and protein-losing enteropathy. TBG can decrease in major systemic illness due to cleavage by leukocyte proteases and reduction in TBG's binding affinity for the thyroid hormones. Both of these effects lower the serum total thyroid hormone concentrations in sick patients (Table 7–1). TBG levels can also decrease chronic thyrotoxicosis, hypercortisolism, and acromegaly. Certain drugs can decrease (androgenic steroids, glucocorticoids, danazol, L-asparaginase) or increase (estrogens, 5-fluourouracil) the plasma TBG concentration. Other drugs (eg, salicylates, high-dose phenytoin, and intravenous furosemide) can bind to TBG, displacing T_4 and T_3. In this circumstance, the hypothalamic-pituitary-thyroid axis (discussed
FIGURE 7–12 Diagrammatic representation of the distribution of radioactive T_4 and T_3 among serum thyroid hormone–binding proteins. **Top:** Paper electrophoretic pattern of serum proteins. **Middle:** Radioactive T_4 was added to serum and was then subjected to paper electrophoresis. Iodine deficiency (with normal serum T_3)[b]

[a]Both total and free T_4 elevated.

[b]Both total and free T_4 low.

later) preserves normal free-hormone concentrations by lowering serum total thyroid hormone levels. Similarly, heparin stimulation of lipoprotein lipase releases free fatty acids that displace thyroid hormones from TBG. *In vivo*, this can result in lower total thyroid hormone concentrations, whereas *in vitro* (eg, in blood drawn through a heparin lock), heparin increases measured levels of free T_4 and T_3.

Transthyretin (Thyroxine-Binding Prealbumin)

Transthyretin, a 55-kD globular polypeptide composed of four identical 127-amino acid subunits, binds 10% of circulating T_4. Its affinity for T_4 is 10-fold greater than for T_3. The dissociation of T_4 and T_3 from transthyretin is rapid, so that transthyretin is a

source of readily available T_4. Increased affinity of transthyretin binding for T_4 can occur as a heritable condition. Affected individuals have an elevated total T_4 but a normal free T_4. Ectopic production of transthyretin, which has been reported to occur in patients with pancreatic and hepatic tumors, also causes euthyroid hyperthyroxinemia.

Albumin

Albumin binds to T_4 and T_3 with lesser affinity than TBG or transthyretin, but its high plasma concentration results in its transport of 15% of circulating T_4 and T_3. Rapid thyroid hormone dissociation rates from albumin make it an additional source of free hormone to tissues. Hypoalbuminemia, as occurs in nephrosis or cirrhosis, is associated with a low total T_4 and T_3, but the free-hormone levels are normal.

Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant inherited disorder in which 25% of the albumin exhibits a higher than normal T_4-binding affinity. This results in an elevated total T_4 level but a normal free T_4 concentration and euthyroidism. In most affected kindreds, the T_3-binding affinity is

normal. Because these albumin variants do not bind the T_4 analogs used in many free T_4 immunoassays, these may falsely report elevation of the free T_4 in affected individuals.

METABOLISM OF THYROID HORMONES

The normal thyroid gland secretes about 100 nmol of T_4 and only 5 nmol of T_3 daily; less than 5 nmol of metabolically inactive reverse T_3 (rT_3) is produced (Figure 7–13). Most of the plasma pool of T_3 (80%) is derived from peripheral outer ring- or 5′-monodeiodination of T_4 in tissues outside of the thyroid gland, particularly the liver, kidney, and skeletal muscle (Table 7–2). Because T_3 has a higher binding affinity for the nuclear T_3 receptors that affect thyroid hormone action, this 5′-monodeiodination generates a more biologically active iodothyronine. On the other hand, deiodination of the *inner* ring of T_4 (5-deiodination) produces 3,3′,5′-triiodothyronine or reverse T_3 (rT_3), which is metabolically inert.

The three deiodinase enzymes that catalyze these reactions differ in tissue localization, substrate specificity, and physiologic and pathophysiologic modulation, as summarized in Table 7–2. Type 1 5′-deiodinase, the most abundant form, is found predominantly in liver and kidney, and in lesser quantities in the thyroid gland, skeletal and heart muscle, and other tissues. The type 1 5′-deiodinase contains a selenocysteine moiety that is probably at the active deiodinating site. The major function of type 1 5′-deiodinase is to provide T_3 to the circulation. Its activity is increased in hyperthyroidism and decreased in hypothyroidism. This partially accounts for the relatively higher circulating T_3 levels compared to T_4 levels seen in hyperthyroid patients. The enzyme is inhibited by the thionamide antithyroid drug PTU, but not methimazole, and by the antiarrhythmic drug amiodarone and iodinated radiocontrast dyes, such as sodium ipodate. Dietary selenium deficiency can also impair T_4 to T_3 conversion.

Type 2 5′-deiodinase is predominantly expressed in the brain and pituitary gland, where it maintains a constant level of intracellular T_3 in the central nervous system. Recent studies also have localized type 2 deiodinase to skeletal muscle, but the relative contribution of type 2 deiodinase derived T_3 to the total circulating pool of T_3 is controversial. This deiodinase is very sensitive to circulating T_4, so a lower circulating T_4 rapidly increases this enzyme's concentration in brain and
FIGURE 7–13 Major pathways of thyroxine metabolism in normal adult humans. Rates are expressed in nmol/24 h and are approximations based upon available data. 100 nmol of T_4 is equivalent to approximately 75 μg. (rT_3, reverse T_3; TETRAC, tetraiodothyroacetic acid.) (Reproduced with permission from Cavalieri RR, Rapoport B. Impaired peripheral conversion of thyroxine to triiodothyronine. *Annu Rev Med.* 1977;28:57-65.)

pituitary—maintaining the intracellular T_3 level and sustaining its neuronal cellular functions. Conversely, elevated plasma T_4 reduces the type 2 5′-deiodinase level, protecting brain cells from excessive T_3. Consequently, this deiodinase represents a mechanism by which the hypothalamus and pituitary can be buffered to some extent from changes in the circulating T_4 level. rT_3 can also modify the activity of type 2 5′-deiodinase in the brain and the pituitary gland; and α-adrenergic compounds stimulate type 2 5′-deiodinase in brown fat, but the physiologic significance of these effects is not clear.

Type 3 5′-deiodinase is found in chorionic membranes of the placenta and glial cells in the central nervous system, where it inactivates T_4 by converting it to rT_3 and it inactivates T_3 by converting it to 3,3′-diiodothyronine (3,3′-T_2) (Figure 7–14). Type 3 deiodinase levels are elevated in hyperthyroidism and decreased in hypothyroidism and, therefore, may help insulate the fetus and the brain from T_4 excess or deficiency. Placental type 3 deiodinase accelerates T_4 disposal in pregnant women, which partly explains the increased T_4 dose requirements in treated hypothyroid women. Congenital and acquired hemangiomas can express high levels of the type 3 deiodinase and cause a rare form of consumptive hypothyroidism.

TABLE 7–2 Iodothyronine deiodinase types and characteristics.

Deiodinase Type	D1	D2	D3
Substrates	$rT_3 > T_4 > T_3$	$T_4 > rT_3$	$T_3 > T_4$
Tissue distribution	Liver, kidney, thyroid	Brain, pituitary, skeletal muscle	Brain, placenta, fetal tissues
Function	Plasma T_3 production	Local and plasma T_3 production	T_3 degradation
PTU inhibition (IC50, μM)	5	>1000	>1000
Hypothyroidism	Decrease	Increase	Decrease
Hyperthyroidism	Increase	Decrease	Increase
FIGURE 7–14 The deiodinative pathway of thyroxine metabolism. The monodeiodination of T_4 to T_3 represents a step-up in biologic potency, whereas the monodeiodination of T_4 to reverse T_3 has the opposite effect. Further deiodination of T_3 essentially abolishes hormonal activity.

Overall, the functions of the deiodinases are physiologically important in three ways. First, they permit local tissue and cellular modulation of thyroid hormone actions. Second, they help the organism adapt to changing states, including iodine deficiency or chronic illness. Third, they regulate thyroid hormone actions in the early development of many vertebrates, including amphibia and mammals.

About 80% of T_4 is metabolized by deiodination, 35% to T_3 and 45% to rT_3 (see Figure 7–13). The remainder is inactivated mainly by glucuronidation in the liver and biliary secretion and, to a lesser extent, by sulfation in the liver or kidney. Other metabolic reactions include deamination of the alanine side chain, forming thyroacetic acid derivatives of low-biologic activity; or decarboxylation or cleavage of the ether link, forming inactive compounds.

As a result of these metabolic pathways, approximately 10% of the total 1000 nmol extrathyroidal T_4 pool is cleared each day, and the plasma half-life of T_4 is 7 days. Due to the lower binding affinity of plasma proteins for T_3, the turnover of its smaller extrathyroidal pool is more rapid, with a plasma half-life of 1 day. The total body pool of rT_3 is about the same size as that of T_3, but rT_3 has an even more rapid turnover, with a plasma half-life of only 0.2 day.

CONTROL OF THYROID FUNCTION AND HORMONE ACTION

Growth and function of the thyroid gland are controlled by the hypothalamic-pituitary-thyroid axis (Figure 7–15) and, as previously discussed, by iodide through the elements of autoregulation.
FIGURE 7–15 The hypothalamic-hypophysial-thyroidal axis. TRH produced in the hypothalamus reaches the thyrotrophs in the anterior pituitary by the hypothalamo-hypophysial portal system and stimulates the synthesis and release of TSH. In both the hypothalamus and the pituitary, it is primarily T_3 that inhibits TRH and TSH secretion, respectively. T_4 undergoes monodeiodination to T_3 in neural and pituitary as well as in peripheral tissues.

Hypothalamic thyrotropin-releasing hormone (TRH) stimulates thyrotrophic cells in the anterior pituitary to produce TSH, which in turn promotes thyroid gland growth and hormone secretion. In addition, deiodinases in the pituitary and peripheral tissues modulate thyroid hormone effects by their tissue-specific conversion of T_4 to the more active iodothyronine T_3. Finally, the molecular effects of T_3 in individual tissues are modulated by the subtype of T_3 receptor with which it interacts; the specific gene activation or repression response that it induces; and in a realm just now being revealed, the T_3 receptor's interaction with other ligands, closely related receptors (eg, retinoid X receptor; RXR), and coactivators and corepressors that interact with it in modulating gene expression. Mutations in the T_3 receptor isoforms cause syndromes of thyroid hormone resistance (see section Resistance to Thyroid Hormone [RTH] Syndromes).

Thyrotropin-Releasing Hormone

TRH is a tripeptide, pyroglutamyl-histidyl-proline amide (pyro-Glu-His-Pro-NH_2), synthesized by neurons in the supraoptic and supraventricular nuclei of the hypothalamus (Figure 7–16). TRH is stored in the median eminence of the hypothalamus and then transported via the pituitary portal venous system down the pituitary stalk to the anterior pituitary, where it controls synthesis and release of TSH. TRH is also found in other portions of the hypothalamus, brain, and spinal cord, where it may have distinct functions as a neurotransmitter. The pre-pro-*TRH* gene, which encodes a large molecule with five copies of the TRH progenitor sequence Glu-His-Pro-Gly, is located on chromosome 3. *TRH* gene expression is negatively regulated by thyroid hormone—both the T_3 delivered by the circulation and that arising from T_4 deiodination in peptidergic neurons themselves (see Table 7–2).

In the anterior pituitary, TRH binds to a specific membrane receptor located on TSH- and prolactin-secreting cells, stimulating synthesis and release of their respective hormones. The TRH receptor is a member of the 7-transmembrane-spanning, G protein–coupled receptor family (Table 1–1; Figure 1–4). TRH binds to the receptor's third transmembrane helix, activating both its cyclic guanosine monophosphate-producing complex and the inositol 1,4,5-triphosphate (IP_3) signaling cascade that releases intracellular Ca^{2+} and generates 1,2-diacylglycerol, thereby activating protein kinase C. These pathways are responsible for stimulating TSH release. They coordinate transcription of the genes encoding the TSH subunits and posttranslational glycosylation of TSH, which is necessary for full biologic activity.

(pyro)Glu-His-Pro-(NH₂)
FIGURE 7–16 Chemical structure of thyrotropin-releasing hormone (TRH).

TRH-stimulated TSH secretion is pulsatile (Figure 7–17), with a mean TSH pulse amplitude of 0.6 mU/L every 2 hours. Normal individuals have a circadian rhythm in TSH release, with a peak circulating level between midnight and 4 AM, which is presumably controlled by a hypothalamic neuronal pulse generator driving TRH synthesis.

Thyroid hormones exert additional negative feedback on TSH production at the level of the pituitary by downregulating the number of TRH receptors on pituitary thyrotropes. Consequently, in patients with hyperthyroidism, both TSH pulses and its nocturnal surge are markedly suppressed; whereas in hypothyroid patients, the TSH pulse amplitude and nocturnal surge are much greater. In experimental animals and newborn humans, exposure to cold temperature increases TRH and TSH secretion. Certain other hormones and drugs (eg, vasopressin and α-adrenergic agonists), stimulate TRH synthesis and release. Leptin also modulates TRH and TSH secretion and may be responsible for the reversible TSH rise seen in some obese patients.

When synthetic TRH is administered intravenously to humans as a 200 to 500 μg bolus, it generates a prompt three- to fivefold rise in the serum TSH concentration, peaking at about 30 minutes and lasting for 2 to 3 hours (see Figure 4–14). In patients with primary hypothyroidism, in whom basal TSH is elevated, there is an exaggerated TSH response to exogenous TRH; and this response is suppressed in patients with hyperthyroidism, high-dose T_4 therapy, and central hypothyroidism.

TRH is also found in the islet cells of the pancreas, gastrointestinal tract, placenta, heart, prostate, testes, and ovaries. TRH production in these peripheral tissues is not inhibited by T_3; the role of TRH in these tissues remains unknown.

Thyrotropin (Thyroid-Stimulating Hormone)

TSH is 28-kD glycoprotein composed of α and β subunits that are noncovalently linked. The α subunit is common to the two other pituitary glycoproteins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), and the placental hormone human chorionic gonadotropin (hCG), whereas the β subunit is unique for each glycoprotein hormone, conferring specific binding properties and biologic activity. The genes for the TSH α and β subunits are located on chromosomes 6 and 1, respectively. The human α subunit has an apoprotein core of 92 amino acids and contains two oligosaccharide chains; the TSH β subunit has an apoprotein core of 112 amino acids and contains one oligosaccharide chain. The α and β subunit amino acid chains of TSH each form three loops that are intertwined into a cystine knot (Figure 7–18). Glycosylation takes place in the RER and the Golgi, where glucose, mannose, and fucose residues and terminal sulfate or sialic acid residues are linked to the apoprotein core. These carbohydrate residues prolong its plasma half-life and enhance it ability to induce TSH receptor activation.

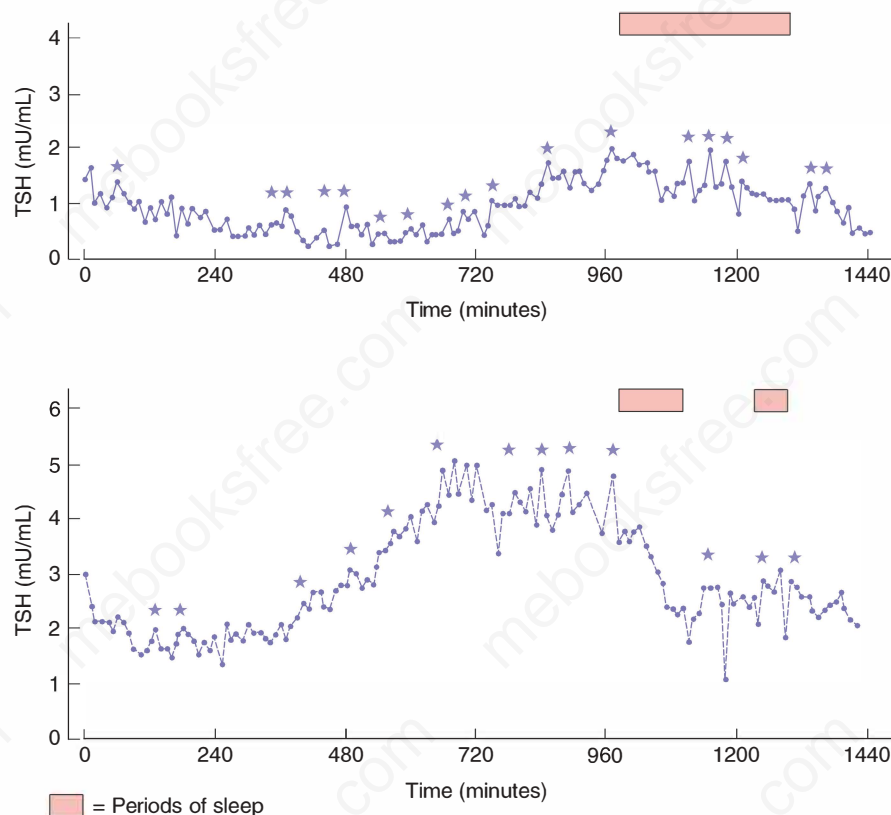
TSH controls thyroid cell growth and hormone production by binding to a specific TSH receptor, one of approximately 1000 located on the basolateral cell membrane of each thyroid cell. TSH binding activates both the cyclic adenosine monophosphate


FIGURE 7–17 Serum TSH in two normal subjects demonstrating spontaneous pulses and the circadian rhythm of TSH secretion. (0 time is 0900; stars indicate significant pulses.) (cAMP) and the phosphoinositol pathways for signal transduction. The TSH receptor gene is located on chromosome 14; the product is a single-chain glycoprotein composed of 764 amino acids. The TSH receptor is a member of the 7-membrane spanning, G protein–coupled receptor family, with an ectodomain involved in ligand binding and an intramembrane and intracellular portion responsible for activation of the signaling pathways that promote thyroid cell growth and hormone synthesis and release (Figure 7–19).

The TSH receptor is involved in the pathogenesis of numerous congenital and acquired forms of hypothyroidism and hyperthyroidism. Heritable defects resulting in impaired TSH synthesis or action have been described, including mutant genes for transcription factors required for pituitary thyrotrope differentiation (*POU1F1, PROP1, LHX3, HESX1*), TRH receptor, TSH β-chain, TSH receptor, and Gsα, which transduces TSH receptor binding to adenylate cyclase activation. Acquired TSH receptor blocking antibodies can also cause hypothyroidism.

The most common TSH receptor–related disorder causing hyperthyroidism is Graves disease, in which autoantibodies bind and stimulate the TSH receptor. However, the TSH receptor is involved in the etiology of several other forms of hyperthyroidism. Germline mutations activating the TSH receptor can cause familial hyperthyroidism, and somatic activating mutations result in toxic adenomas. Other mutations can lead to aberrant TSH receptor activation by hCG, the placental glycoprotein hormone that is structurally similar to TSH, in familial gestational hyperthyroidism.

Effects of TSH on the Thyroid Cell

TSH has many actions on the thyroid cell. Most of its actions are mediated through the G protein-adenylyl cyclase-cAMP system, but activation of the phosphatidylinositol (PI) system with a resulting increase in intracellular calcium is also involved. The major actions of TSH include the following:

A. Changes in thyroid cell morphology TSH rapidly induces pseudopods at the follicular cell–colloid border, accelerating TG resorption. Colloid content is diminished as intracellular colloid droplets are formed, and lysosome formation is stimulated, increasing TG hydrolysis and thyroid hormone release.

B. Cell growth Individual thyroid cells increase in size; vascularity is increased; and, over a period of time, thyroid enlargement, or goiter, develops.

C. Iodine metabolism TSH stimulates all phases of iodide metabolism, from increased iodide uptake and transport to increased iodination of TG and increased secretion of thyroid hormones and TG itself. Increased NIS expression and
FIGURE 7–18 Schematic configuration of the TSH-TSHR complex. The central portion of the figure represents the ribbon-like structure of TSH within the TSH receptor. The pink line represents the β subunit and the yellow line the α subunit. See also Figure 7–19. (Data from Kajava AV, Vassart G, Wodak SJ. Modeling of the three-dimensional structure of proteins with the typical leucine-rich repeats. *Structure*. 1995 Sep 15;3(9):867-877.)

the stimulation of cAMP production mediate increased iodide transport, and phosphatidylinositol-4,5-bisphosphate (PIP_2) hydrolysis and increased intracellular Ca^{2+} stimulate the iodination of TG. The TSH effect on thyrocyte iodide content is biphasic: initially, it is decreased (iodide efflux) due to the rapid increase in hydrolysis of TG with release of hormone and leakage of iodide out of the gland; and then after a lag of several hours, iodide uptake is increased. The TSH-mediated stimulation of thyrocyte iodine uptake and TG secretion also occur after administration of recombinant TSH for radioiodine treatment and monitoring of patients with well-differentiated thyroid cancers.

D. Other effects of TSH   Other effects include increased transcription of the mRNAs for TG and TPO; increased incorporation of iodide into MIT, DIT, T_3, and T_4; and increased

lysosomal activity, with increased secretion of T_4 and T_3 from the gland. There is also increased activity of type 1 5′-deiodinase, which helps conserve intrathyroidal iodine.

TSH has additional effects on the thyroid gland, including stimulation of glucose uptake, oxygen consumption, and glucose oxidation—effects that can enhance detection of thyroid cancer metastases by Fluorodeoxyglucose Positron Emission Tomography (FDG PET) scanning. There is accelerated turnover of phospholipids and stimulation of synthesis of purine and pyrimidine precursors, with increased synthesis of DNA and RNA.

Serum TSH

Intact TSH and isolated α subunit are both present in circulating blood and detectable by immunoassay in concentrations that are
FIGURE 7–19 Schematic representation of the TSH receptor. The A subunit is the ligand-binding portion of the receptor and the B subunit is the activation portion. The ligands which bind to the receptor include TSH, TSH-stimulating antibody, and TSH-blocking antibody. There are two cleavage sites which allow breakage of the receptor and loss of the A subunit into the serum. (Reproduced with permission from Rapoport B, Chazenbalk GD, Jaume JC, et al. The thyrotropin (TSH) receptor: interaction with TSH and autoantibodies. *Endocr Rev*. 1998 Dec;19(6):673-716.)

normally 0.5 to 4.0 mU/L and 0.5 to 2 μg/L, respectively. The serum TSH level is increased in primary hypothyroidism and decreased in thyrotoxicosis, whether endogenous or from excessive oral intake of thyroid hormones. The plasma half-life of TSH is about 30 minutes, and the daily production rate is about 40 to 150 mU/d.

The glycoprotein α subunit is often disproportionately elevated in patients with TSH-secreting pituitary tumors (see later); it is also increased in normal postmenopausal women due to increased synthesis and secretion related to increased gonadotropin production.

Control of Pituitary TSH Secretion

Two major factors control synthesis and release of TSH: (1) T_3 level within thyrotroph cells, which regulates mRNA expression, TSH translation, and the hormone's release; and (2) TRH, which controls posttranslational glycosylation and also release.

TSH synthesis and release are inhibited by high serum levels of T_4 and T_3 (thyrotoxicosis) and stimulated by low levels of thyroid hormone (hypothyroidism). Thyrotoxicosis can suppress serum TSH levels beneath the limits of assay detection, and recovery of normal TSH secretion may require weeks or months after restoration of normal thyroid hormone levels. Certain other hormones and drugs can also inhibit TSH secretion. These include somatostatin, dopamine, dopamine agonists such as bromocriptine, and high doses of glucocorticoids—all of which typically lower the circulating TSH level, but do not suppress it completely. Severe systemic illnesses can inhibit TSH secretion, and there may be a rebound increase in TSH as the patient recovers. In contrast, overt hyperthyroidism can suppress the TSH concentration to beneath the detection limits of even the most sensitive TSH immunoassays.

Tumors and other disorders of the hypothalamus or anterior pituitary gland can impair TRH and TSH secretion, respectively. Pituitary disorders causing hypothyroidism are termed *secondary*, whereas hypothalamic disease resulting in hypothyroidism is called *tertiary*. Differential diagnosis of these lesions is discussed later (see Thyroid Tests).

Other Thyroid Stimulators and Inhibitors

Growth factors such as insulin, insulin-like growth factor-1, insulin-like growth factor binding proteins, epidermal growth factor, transforming growth factor β1, and fibroblast growth factors and their receptors, as well as autocrine factors such as prostaglandins and cytokines, modify thyroid cell growth and hormone production. Some of these may be involved in the pathogenesis of benign nodular goiter. The thyroid follicle has a rich supply of capillaries that are accompanied by noradrenergic nerve fibers from the superior cervical ganglion and acetylcholine esterase-positive nerve fibers derived from the vagus nerve and thyroid ganglia. However, these are not known to play any role in thyroid gland regulation. The parafollicular C cells secrete both calcitonin and calcitonin gene-related peptide (CGRP). In experimental animals, these and other neuropeptides modify thyroid blood flow and hormone secretion.

The Actions of Thyroid Hormones
1. THE THYROID HORMONE RECEPTORS AND MECHANISMS OF ACTION

The thyroid hormones exert their actions through two general mechanisms: (1) genomic actions effected through T_3 interactions with its nuclear receptors, regulating gene activity; and

		T₃ binding	DNA binding
FIGURE 7–20 Deduced protein structure of the thyroid hormone receptor α and β gene products. The receptor protein has three domains: a DNA-binding domain with a high degree of similarity among the different types of receptors, a carboxyl terminal triiodothyronine (T_3)–binding domain, and an amino terminal domain that is not required for full function. The numbers above the structures represent amino acid numbers. The properties of the receptors with respect to their ability to bind T_3 and bind to a T_3-response element of DNA are shown on the right. Identical shading of receptor domains indicates identical amino acid sequences. (TR, thyroid hormone receptor.) (Reproduced with permission from Brent GA. The molecular basis of thyroid hormone action. *N Engl J Med*. 1994 Sep 29;331(13):847-853.)

(2) nongenomic actions mediated by T_3 and T_4 interactions with certain enzymes (eg, calcium ATPase, adenylate cyclase, and monomeric pyruvate kinase), glucose transporters, mitochondrial, and membrane proteins.

Thyroid hormones, that are unbound in plasma, are transported intracellularly, by either specific carriers including monocarboxylate transporter 8 (MCT8), MCT10, and organic anion transporting polypeptide (OATP1C1). OATP1C1 is expressed predominantly in brain capillaries and the choroid plexus, and transports T_4 preferentially, while MCT8 and MCT10 are expressed in many tissues and transport both T_4 and T_3. Thyroid hormones are transported through the cell membrane into the cytoplasm, and subsequently into the nucleus, where T_3 binds to its specific receptor. Clinical syndromes associated with mutations in these transporters have recently been recognized, such as the Allan-Herndon-Dudley syndrome in which affected male children develop mental retardation, myopathy, and a movement disorder in association with elevated serum T_3 and low serum T_4 levels.

The T_3 nuclear receptor is member of a nuclear receptor superfamily that includes nuclear receptors for glucocorticoids, mineralocorticoids, estrogens, progestins, vitamin D_3, and retinoids (see Figure 1–16). There are two thyroid hormone receptor (*TR*) genes in humans: *TR*α located on chromosome 17 and *TR*β on chromosome 3. Each gene yields at least two differentially spliced products, TRα 1 and 2 and TRβ 1 and 2, although TRα 2 is believed to be biologically inactive (Figure 7–20). Each of these receptors has a carboxyl terminal ligand-binding domain and a centrally located DNA-binding domain with two cysteine zinc fingers that facilitate their specific attachment to thyroid hormone response elements (TREs) in the promoters of target genes and regulate their transcription (see Figures 1–16 and 1–17). The concentration of these receptors in tissue varies among tissues and with their stage of development. For example, the brain contains predominantly TRα, the liver mostly TRβ, and cardiac muscle contains both. Point mutations in the ligand-binding domain of the *TR*β gene have been shown to be responsible for the syndrome of generalized resistance to thyroid hormone (GRTH). The TRs bind to TREs, which are typically paired, specific oligonucleotide sequences (eg, AGGTCA) (Figure 7–21). The TRs can also function as heterodimers with receptors for other transcription factors, such as the retinoid X and retinoic acid receptors. TREs are generally located upstream of the transcription start site for the coding regions of thyroid hormone–responsive genes. In positively regulated genes, unbound TRs interact with corepressors (eg, nuclear receptor corepressor [NCoR] and silencing mediator for retinoic and thyroid hormone receptors [SMRT]) to repress basal transcription by recruiting histone deacetylases that alter the nearby chromatin structure. When TRs are bound by T_3, these corepressor complexes are released, and the T_3-bound TRs associate with coactivator complexes that promote local histone acetylation. They also associate with another protein complex (vitamin D receptor-interacting protein/TR-associated proteins) that recruits RNA polymerase II and starts gene transcription. Some genes are negatively regulated by T_3-bound TRs, such as pre-pro-*TRH* and *TSH*-α and -β subunit genes. Thyroid hormone's actions to alter expression levels of specific mRNAs and their translated proteins generate a constellation of specific tissue responses (see Figure 7–21).

Additional nongenomic actions of thyroid hormones have long been suspected based on certain rapid tissue responses that take place before RNA transcription could occur and by recognition of T_3- and T_4-binding sites outside of the nucleus. For example, it has been shown that thyroid hormones bind the membrane protein integrin αVβ3, which is involved in thyroid hormone–mediated activation of the MAP kinase cascade and stimulation of angiogenesis.

2. PHYSIOLOGIC EFFECTS OF THYROID HORMONES

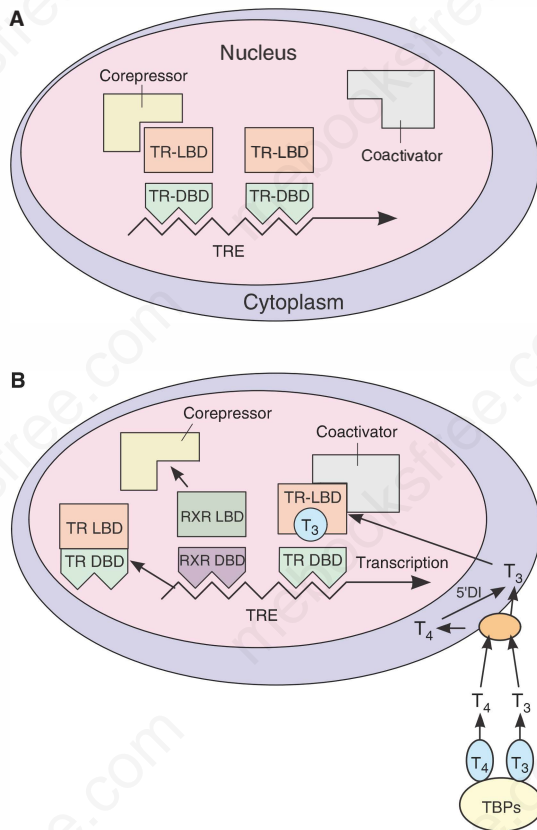
The transcriptional effects of T_3 characteristically demonstrate a lag time of hours or days to achieve full effect. These genomic actions have a number of vital effects, including tissue growth,


FIGURE 7–21 Model of the interaction of T_3 with the T_3 receptor. **Panel A, Inactive Phase:** The unliganded T_3 receptor dimer bound to the TRE along with corepressors acts as a suppressor of gene transcription. **Panel B, Active Phase:** T_3 and T_4 circulate bound to thyroid-binding proteins (TBPs). The free hormones are transported into the cell by a specific transport system. Within the cytoplasm, T_4 is converted to T_3 by 5′-deiodinase and T_3 moves into the nucleus. There it binds to the ligand-binding domain of the TR monomer. This promotes disruption of the TR homodimer and heterodimerization with RXR on the TRE, displacement of corepressors, and binding of coactivators. The TR-coactivator complex activates gene transcription, which leads to alteration in protein synthesis and cellular phenotype. (TR-LBD, T_3 receptor ligand-binding domain; TRDBD, T_3 receptor DNA-binding domain; RXR-LBD, retinoid X receptor ligand-binding domain; RXR-DBD, retinoid X receptor DNA-binding domain; TRE, thyroid hormone response element; TBPs, thyroxine-binding proteins; T_3, triiodothyronine; T_4, tetraiodothyronine, L-thyroxine; 5′DI, 5′-deiodinase.)

brain maturation, increased calorigenesis and oxygen consumption, as well as other specific effects on the heart, liver, kidneys, skeletal muscle, and skin. However, as noted earlier, some actions of T_3 are believed not to be genomic, including its reduction of pituitary type 2 5′-deiodinase activity and the increased glucose and amino acid transport that it can induce in some tissues. Some specific effects of thyroid hormones are summarized later.

Effects on Fetal Development

Iodide concentration by thyroid tissue and pituitary TSH both appear in the human fetus at about 11 weeks of gestation. Because

of the high placental content of type 3 5′-deiodinase, most maternal T_3 and T_4 are inactivated, and very little free hormone reaches the fetal circulation. However, this small amount of free hormone from the mother may be important for early fetal brain development. After 15 to 18 weeks of gestation, the fetus is largely dependent on its own thyroidal secretion. Although some fetal growth occurs in the absence of fetal thyroid hormone secretion, brain development and skeletal maturation are markedly impaired if congenital hypothyroidism is undiagnosed and thyroid hormone therapy is not begun promptly after birth. Congenital hypothyroidism results in cretinism, the features of which include mental retardation and dwarfism.

Effects on Oxygen Consumption, Heat Production, and Free Radical Formation

T_3 increases O_2 consumption and heat production in part by stimulation of Na$^+$-K$^+$ ATPase in all tissues except the brain, spleen, and testis. This contributes to the increased basal metabolic rate (total somatic O_2 consumption at rest) and the increased sensitivity to heat in hyperthyroidism—and the opposite in hypothyroidism. Thyroid hormones stimulate mitochondriogenesis, augmenting the cell's oxidative capacity. They also induce changes in the mitochondrial inner membrane protein and lipid composition that increase oxidative metabolism by both genomic and nongenomic effects. The reduced efficiency of oxidative metabolism caused by thyroid hormone is also reflected in the increased futile cycling of intermediary carbohydrate metabolites.

Cardiovascular Effects (Figure 7–22)

T_3 stimulates transcription of sarcoplasmic reticulum Ca^{2+} ATPase, increasing the rate of myocardial diastolic relaxation. It also increases expression of the more rapidly contractile α isoform of myosin heavy chain, which contributes to enhanced systolic function. In myocardium, T_3 also alters expression of different isoforms of the Na$^+$-K$^+$ ATPase genes, increases expression of α-adrenergic receptors, and decreases the concentration of the inhibitory G protein Gi α. Thyroid hormones also lower peripheral vascular resistance and increase intravascular volume, which contribute further to the increase in cardiac output associated with thyroid hormone action. T_3 also increases the rates of both depolarization and repolarization of the sinoatrial node, increasing heart rate. Consequently, thyroid hormones have positive chronotropic and inotropic effects on the heart, which, along with the heightened adrenergic sensitivity (see later), account for the increased heart contractility and rate in hyperthyroidism and the reverse in hypothyroidism.

Sympathetic Effects

Thyroid hormones increase the number of β-adrenergic receptors in heart and skeletal muscle, adipose tissue, and lymphocytes.
FIGURE 7–22 Sites of action of triiodothyronine on cardiac myocytes. Triiodothyronine enters the cell, possibly by a specific transport mechanism, and binds to nuclear triiodothyronine receptors. The complex then binds to thyroid hormone response elements of target genes and regulates transcription of these genes. Nonnuclear thyroid hormone effects on ion channels also occur. (Reproduced with permission from Klein I, Ojamaa K. Thyroid hormone and the cardiovascular system. *N Engl J Med.* 2001 Feb 15;344(7):501-509.)

They may also amplify catecholamine action at a postreceptor site. Many of the clinical manifestations of thyrotoxicosis appear to reflect increased sensitivity to catecholamines. Furthermore, therapy with β-adrenergic–blocking agents is often helpful in controlling these sympathomimetic manifestations of thyroid hormone excess.

Pulmonary Effects

Thyroid hormones maintain ventilatory responsiveness to hypoxia and hypercapnia in the brain stem respiratory center. Consequently, in patients with severe hypothyroidism, hypoventilation can occur. Respiratory muscle functions are also regulated by thyroid hormone, and can be weakened in hyperthyroidism, leading to a sense of breathlessness.

Hematopoietic Effects

The increased cellular demand for O_2 in hyperthyroidism leads to increased production of erythropoietin and increased erythropoiesis. However, blood volume is usually not increased because of hemodilution and increased red cell turnover. Thyroid hormones increase the 2,3-diphosphoglycerate content of erythrocytes, allowing increased O_2 dissociation from hemoglobin and increasing O_2 availability to tissues. The reverse occurs in hypothyroidism.

Gastrointestinal Effects

Thyroid hormones promote gut motility, which can result in increased motility and hyperdefecation (ie, increased frequency of formed bowel movements) in hyperthyroidism. Conversely, slowed bowel transit and constipation occur in hypothyroidism.

Skeletal Effects

Thyroid hormones stimulate bone turnover, increasing bone resorption and, to a lesser degree, bone formation. Consequently, hyperthyroidism can be associated with hypercalciuria, and less often, hypercalcemia. Furthermore, chronic thyroid hormone excess can cause clinically significant bone mineral loss and increased fracture risk.

Neuromuscular Effects

In hyperthyroidism, there is increased protein turnover and loss in skeletal muscle, which can lead to a characteristic proximal myopathy. There is also an increase in the speed of muscle contraction and relaxation, noted clinically as the hyperreflexia of hyperthyroidism, and the delayed deep tendon reflex relaxation phase in hypothyroidism. A fine distal hand tremor is also typical in hyperthyroidism. As noted earlier, thyroid hormones are essential for normal development and function of the central nervous system, and failure of fetal thyroid function results in severe mental retardation. In the adult, hyperactivity in hyperthyroidism and sluggishness in hypothyroidism can be striking. Similarly, hyperthyroid patients can be anxious or agitated, while hypothyroidism is typically associated with a depressed mood.

Effects on Lipid and Carbohydrate Metabolism

Hyperthyroidism increases hepatic gluconeogenesis and glycogenolysis, as well as intestinal glucose absorption, and there may also be thyroid hormone–mediated decreases in insulin sensitivity. Thus, hyperthyroidism can worsen glycemic control in patients who also have diabetes mellitus. Cholesterol synthesis and degradation are both increased by thyroid hormones. The latter effect is due largely to an increase in hepatic low-density lipoprotein (LDL) receptor number, accelerating LDL clearance. Consequently, total and LDL cholesterol levels are typically elevated in patients with hypothyroidism. In hyperthyroidism, lipolysis is increased, releasing fatty acids and glycerol into circulating plasma.

Endocrine Effects

Thyroid hormones alter the production, responsiveness, and metabolic clearance of a number of hormones. In hypothyroid children, impaired growth hormone release slows longitudinal growth. Hypothyroidism can cause delayed puberty by impairing gonadotropin-releasing hormone (GnRH) and gonadotropin secretion. Conversely, primary hypothyroidism can also cause precocious puberty, perhaps as an effect of very high TSH levels on gonadotropin receptors. In adults, hypothyroidism causes hyperprolactinemia in a minority of affected women. Menorrhagia (prolonged and heavier menses) and anovulation are common in hypothyroid women, the latter resulting in infertility. The responsiveness of the hypothalamic-pituitary-adrenal axis to stress is blunted in hypothyroid patients. A slowing of the cortisol metabolic clearance rate compensates for this in the hypothyroid state. Conversely, however, restoration of euthyroidism can rarely provoke adrenal insufficiency as cortisol metabolism is accelerated in patients with diminished cortisol reserve due to concomitant disease affecting the adrenal axis.

In hyperthyroidism, accelerated aromatization of androgens to estrogens and increased sex hormone–binding globulin levels contribute to the gynecomastia and elevated total testosterone levels seen in affected men. Hyperthyroidism can also impair normal GnRH and gonadotropin regulation of ovulation and menses, causing infertility and amenorrhea, respectively. All of the endocrine derangements occurring with thyroid dysfunction are reversed by appropriate treatment to restore euthyroidism.

PHYSIOLOGIC CHANGES IN THYROID FUNCTION

Thyroid Function in the Fetus

Before the fetus develops its own independent thyroid function, it depends on maternal thyroid hormones for early neural development. By the 11th week of gestation, however, the hypophysial portal system has developed, and measurable TSH and TRH are present. At about the same time, the fetal thyroid begins to trap iodine. The secretion of thyroid hormone probably begins in mid gestation (18-20 weeks). TSH increases rapidly to peak levels at 24 to 28 weeks, and T_4 levels peak at 35 to 40 weeks. T_3 levels remain low during gestation; T_4 is converted to rT_3 by type 3 5′-deiodinase during fetal development. At birth, there is a sudden marked rise in TSH stimulated by exposure to the colder extrauterine environment, with a rise in T_4, a rise in T_3, and a fall in rT_3. These parameters gradually stabilize over the first month of life.

Thyroid Function in Pregnancy

A number of thyroid parameters change during pregnancy. There is an increase in urinary iodide clearance; in areas of low dietary iodine intake, this can lead to maternal goiter, or when severe, hypothyroidism. During pregnancy, there is a rise in TBG due to an estrogen-induced increase in hepatic glycosylation of TBG, prolonging its metabolic clearance rate. Consequently, serum total T_4, and to a lesser extent, total T_3 concentrations rise. Rising levels of hCG, which has weak TSH receptor agonist activity, contribute to minimal thyroid enlargement. Maternal hCG levels peak at approximately 12 weeks resulting in a transient high-normal or even modestly elevated serum-free T_4 level and a physiologic suppression of serum TSH to the low-normal or even subnormal range. Pathologically elevated hCG levels, found in women with a molar pregnancy or choriocarcinoma, can cause overt hyperthyroidism. Women with severe vomiting in pregnancy, called hyperemesis gravidarum, may also have higher levels of hCG, and can develop transient gestational thyrotoxicosis. As noted earlier, placental type 3 deiodinase accelerates T_4 clearance during pregnancy, which partly accounts for the increased T_4 dose requirement in treated hypothyroid women, and occasionally causes mild hypothyroidism in women with autoimmune thyroiditis and decreased thyroid gland reserve.

Transplacental delivery of thyroid-related substances can have consequences for the fetus. Maternal iodide crossing the placenta is essential for fetal thyroid hormone production; however, large amounts of iodide can actually inhibit fetal thyroid function and cause a goiter substantial enough to obstruct delivery. In women with autoimmune thyroid disease, maternal immunoglobulins that stimulate or block the TSH receptor can cross the placenta and cause thyroid dysfunction in the fetus. The antithyroid drugs methimazole and PTU cross the placenta, and in large doses will impair fetal thyroid function (see Chapter 16).

Changes in Thyroid Function with Aging

T_4 turnover is highest in infants and children, and gradually falls to adult levels after puberty. The T_4 turnover rate is then stable until after age 60, when it again begins to decline. In the elderly, the metabolic clearance of T_4 can decrease by as much as 50%, necessitating a reduction in T_4 dose for treated hypothyroid patients.

Effects of Acute and Chronic Illness on Thyroid Function (Euthyroid Sick Syndrome)

Acute or chronic illness has several striking effects on thyroid function and hormone economy. The most common and earliest effect is inhibition of T_4-to-T_3 conversion, with a resulting decrease in the circulating T_3 level. This change is accompanied by a rise in the serum rT_3 level, due to both its decreased conversion to $3,3'$-T_2 and some acceleration of its production from T_4. These changes occur physiologically in the fetus and pathologically in circumstances of caloric restriction, as in malnutrition, starvation, and anorexia nervosa, and in patients with a variety of acute or chronic systemic illnesses (Table 7–3). The pathogenesis of this *low T_3 syndrome* is thought to involve cytokines, such as tumor necrosis factor, secreted by inflammatory cells, which inhibit type 1 $5'$-deiodinase. Drugs can also inhibit type 1 $5'$-deiodinase and lower the serum T_3 levels in treated patients; these agents include corticosteroids, amiodarone, iodinated cholecystographic dyes,

PTU, and high-dose propranolol. Initially, low serum T_3 levels are typically accompanied by total and free T_4 levels that are normal or, less commonly, slightly elevated (Figure 7–23). As illness becomes more severe, however, there is a decline in serum total and free T_4 as well. This hypothyroxinemia can have several causes. In certain illnesses (eg, nephrosis and severe liver disease), there can be a decline in the circulating TBG concentration. A rise in plasma free fatty acids can interfere with T_4 binding to TBG, liberating more free T_4 that, in turn, feeds back on the hypothalamus and pituitary to reduce TSH and establish a new equilibrium with a lower total T_4. TSH can also be suppressed by cytokines circulating in severely ill patients and by the dopamine or corticosteroids often used to treat critically ill patients. Finally, T_4 clearance is accelerated in illness. All of these factors can contribute to the lower serum levels of T_4 and free T_4, as measured by free-hormone immunoassays and estimated T_3 resin-uptake procedures. However, the free T_4 level measured by equilibrium dialysis has been reported to be normal in most, but not all patients.

Two clinical questions arise in sick patients with this constellation of thyroid function test abnormalities. First, it can be challenging to distinguish the euthyroid sick syndrome from central hypothyroidism; in both conditions, the T_4 and TSH levels can be low. Clinical information can be helpful, including a history of known pituitary or thyroid disease, head trauma or surgery, or

FIGURE 7–23 A schematic representation of the changes in serum thyroid hormone values with increasing severity of nonthyroidal illness. A rapidly rising mortality rate accompanies the fall in serum total T_4 (TT_4) and free T_4 (FT_4) values. (Reproduced with permission from Hurst JW. *Medicine for the Practicing Physician,* 2nd ed. Philadelphia: Butterworth-Heinemann; 1991.)

manifestations of other elements of hypopituitarism (eg, small testes in a man). Additional laboratory testing can sometimes be informative. The serum-free T_4 level determined by equilibrium dialysis is typically normal in the euthyroid sick syndrome. In postmenopausal women, an elevated serum FSH attests to at least one intact pituitary function, although gonadotropin levels can be low in severe illness as well. Measurement of serum cortisol may be particularly helpful, because it should be normal or elevated in any patient with significant systemic illness. If it is normal or elevated, hypothalamic or pituitary disease is most unlikely. Sometimes, however, it is necessary to obtain emergent imaging of the hypothalamus or pituitary to resolve the question. These thyroid function test abnormalities normalize when the patient recovers. However, recovery can be accompanied by transient rebound elevation of the serum TSH that could be misinterpreted as hypothyroidism. In this setting, in the absence of clinically apparent hypothyroidism, it is best to avoid thyroid hormone therapy and to reevaluate a few weeks following recovery.

The second clinical question is whether the euthyroid sick syndrome itself should be treated with thyroid hormone. Certainly, many critically ill patients have clinical problems that are reminiscent of hypothyroidism, such as hypothermia, altered sensorium, ventilatory and myocardial dysfunction, and hyponatremia. It has been postulated that intracellular hypothyroidism may exist in these patients and that thyroid hormone therapy might be beneficial. Conversely, it has been proposed that these changes in thyroid status are, in fact, compensatory mechanisms for reducing rates of oxygen consumption and protein catabolism and that thyroid hormone therapy might actually be harmful. Furthermore, two small randomized trials, small clinical series, and animal models of systemic illness all have failed to demonstrate any benefit of thyroid hormone therapy in this setting. Although the issue remains unresolved, current practice is generally to withhold thyroid hormone therapy, unless there is convincing clinical and biochemical evidence of true hypothyroidism.

THYROID AUTOIMMUNITY

Autoimmunity is involved in the pathogenesis of many thyroid diseases, including hyperthyroid Graves disease, hypothyroidism with autoimmune or Hashimoto thyroiditis, silent and postpartum thyroiditis, and certain forms of neonatal thyroid dysfunction. Immunologic defense against foreign organisms and substances and neoplastic cells involves macrophages that ingest and digest the foreign material and present peptide fragments on the cell surface in association with a class II protein encoded by the HLA-DR region of the *MHC* gene complex. This complex is recognized by a T-cell receptor on a CD4 helper T cell, which stimulates the release of cytokines such as interleukin-2 (IL-2). These cytokines amplify the response by inducing T-cell activation and proliferation, induction of killer cell activity in CD8 suppressor cells, and stimulation of Ab formation against the foreign antigen by B lymphocytes. Eventually, the activation process is muted by the action of the CD8 suppressor cells (see Chapter 2).

Early histopathological and experimental observations suggested the possibility that immunologic reactions could affect the thyroid gland. Thyroiditis was induced by immunization of mice with thyroid tissue and Freund adjuvant. TG Abs were identified in the sera from patients with thyroiditis, and a long-acting thyroid stimulator, later shown to be an Ab to the TSH receptor, was found in the sera of patients with Graves disease.

There are three major thyroidal antigens that can incite autoantibodies: TG, TPO, and TSH receptor. Circulating autoantibodies to these antigens are useful markers for thyroid autoimmunity, but T-cell-mediated immune mechanisms are central to the pathogenesis of thyroid diseases. Thyroid cells have the capacity to ingest antigen (eg, TG) and, when stimulated by cytokines such as gamma interferon, express cell surface class II molecules (eg, HLA-DR4) that present these antigens to T lymphocytes. In addition to the antigen and the class II molecule, other factors, such as costimulatory signals from antigen-presenting cells, are doubtless required to initiate autoimmune thyroid disease. One hypothesis is that the process is initiated or promoted by external antigens (eg, infectious agents) that lead to thyroid-directed Ab and cellular immune responses through cross-reactivity. In addition, genetic factors clearly predispose individuals to thyroid autoimmunity. HLA typing in patients with Graves disease reveals a high frequency of HLA-B8 and HLA-DR3 in Caucasians, HLA-Bw46 and HLA-B5 in Chinese, and HLA-B17 in blacks. In Caucasians, atrophic thyroiditis has been associated with HLA-B8 and goitrous Hashimoto thyroiditis with HLA-DR5. It has been suggested that a genetically-induced, antigen-specific defect in suppressor T lymphocytes may be the basis for autoimmune thyroid disease.

The increased incidence of autoimmune thyroid disease in postpubertal and premenopausal women, as well as the occurrence of postpartum thyroiditis, implies a possible role for female sex hormones or X-linked genes in the pathogenesis of autoimmune thyroid disease. A high-iodine intake may result in more highly iodinated TG that is more immunogenic and would favor the development of autoimmune thyroid disease. Therapeutic doses of lithium, used for the treatment of bipolar disorder, can interfere with suppressor cell function and may precipitate autoimmune thyroid disease.

TESTS OF THYROID FUNCTION

The high prevalence of thyroid dysfunction and neoplasia make testing for thyroid disease a daily necessity in virtually every field of medical practice—whether a pediatrician screening a neonate for congenital hypothyroidism, an internist considering possible thyroid dysfunction in a patient with nonspecific complaints, an obstetrician-gynecologist evaluating a woman with infertility, a surgeon or radiologist starting assessment of a patient with a thyroid nodule, or virtually any type of specialist considering thyroid disease as the potential cause for a complaint or test abnormality in their field of interest (eg, cardiologist, gastroenterologist, neurologist, psychiatrist, and ophthalmologist).

Several levels of laboratory and radiologic investigation for thyroid diseases should be considered. First, it is common for clinicians with a relatively low index of suspicion for thyroid dysfunction in a particular patient to want to exclude its presence

with greater certainty. For this purpose, a test with high sensitivity (ie, few false-negative results), wide availability, and low cost is most appropriate. The serum TSH concentration often plays this role in clinical consideration of hypothyroidism and hyperthyroidism. Second, when suspicion of thyroid disease is moderate to high, based on clinical or other routine laboratory results, testing with even greater sensitivity to detect even rare thyroid disorders is required, and which also begins to define the severity and underlying cause of thyroid dysfunction. For example, in a patient with hypothermia, confusion, periorbital edema, and hypercholesterolemia, measurement of both the serum TSH and free T_4 concentrations would permit exclusion of both primary and central forms of hypothyroidism; furthermore, if hypothyroidism is confirmed, the site of responsible disease would be implicated. Third, when thyroid dysfunction is clinically obvious or already biochemically confirmed by first-line testing, then more sophisticated studies are sometimes indicated to identify the underlying cause and plan appropriate therapy. For example, in a postpartum woman with thyrotoxicosis, an additional serum T_3, thyroid-stimulating immunoglobulin (TSI), and radionuclide thyroid uptake may be needed to differentiate Graves disease and postpartum thyroiditis—for which there are distinct therapeutic approaches.

TESTS OF THYROID HORMONES IN BLOOD

Serum TSH Measurement

Because thyroid dysfunction usually arises from primary disorders of the thyroid gland, serum TSH measurement is the most widely employed test to determine whether thyroid dysfunction exists. The sensitivity of the hypothalamic-pituitary-thyroid axis ensures that both primary hypothyroidism and thyrotoxicosis, due to either primary thyroid disorders or exogenous thyroid hormones, are detected. Furthermore, even mild degrees of thyroid dysfunction, in which the serum thyroid hormone concentrations have fallen or risen significantly but remain within the broad reference range (ie, subclinical or mild thyroid dysfunction) are identified. The inverse logarithmic relationship between serum TSH and free T_4 concentration in various situations is shown in Figures 7–24A and 7–24B.
FIGURE 7–24 **A.** Relationship between serum-free thyroxine by dialysis (FT_4) ng/dL and $\log_{10}$ TSH in euthyroid, hyperthyroid, hypothyroid, and T_4-suppressed euthyroid individuals. Note that for each unit change in T_4 there is a logarithmic change in TSH. **B.** Relationship between FT_4 by dialysis and $\log_{10}$ TSH in normal subjects and subjects with various illnesses including primary hypothyroidism, central hypothyroidism and non–levothyroxine-suppressed TSH, levothyroxine-treated congenital hypothyroidism, TSH-secreting tumors, thyroid hormone resistance, nonthyroidal illness, and nonpituitary hyperthyroidism. (Reproduced with permission from Kaptein EM. Clinical applications of free thyroxine determinations. *Clin Lab Med.* 1993 Sep;13(3):653-672.)
FIGURE 7–24 *(Continued)*

TSH assays must be sensitive (ie, able to distinguish low from very low and undetectable TSH levels) to be used for diagnosis of thyrotoxicosis. A National Academy of Clinical Biochemistry guideline specifies that sensitivity, or lower limit of detection, for TSH assays should be less than 0.02 mU/L. It is better to assess and compare TSH assays by this quantitative criterion rather than marketing terms such as *third-generation* or *ultrasensitive*.

There are, in general, two sorts of immunoassays used to measure TSH (and T_4 and T_3) in serum samples: immunometric assays (IMA) and radioimmunoassay (RIA). In an IMA or *sandwich assay*, an Ab—usually a mouse monoclonal Ab—directed against one epitope on the TSH molecule is fixed to a solid matrix, and a second monoclonal TSH Ab that binds another TSH epitope is labeled with a detectable marker, which can be a radioisotope, a colorimetrically quantifiable enzyme, or a fluorescent or chemiluminescent tag. In such IMAs, the concentration of TSH, which links the solid state and labeled Abs, is proportionate to the intensity of signal emitted by the marker once unbound second Ab has been separated off. In contrast, in conventional RIAs, a small amount of a TSH tracer, to which a radioactive molecule has been linked, competes for binding to first Ab (eg, a rabbit antihuman TSH polyclonal Ab). Then Ab-bound TSH, both in the sample and the tracer, is separated from the free tracer in the supernatant using one of several techniques: a second Ab directed against the first (eg, goat antirabbit immunoglobulin Ab), polyethylene glycol, or staphylococcal protein A. In RIAs, the concentration of TSH in the sample is inversely proportionate to tracer activity. In general, TSH IMAs are more sensitive and widely employed than RIAs.

There are infrequent but important limitations of the serum TSH assay alone for diagnosis of thyroid dysfunction when clinical suspicion of hypothyroidism is high and in certain other special circumstances (Table 7–4). First, central hypothyroidism can be overlooked. In patients with hypothyroidism due to a pituitary tumor, for example, the serum TSH is typically not markedly elevated, but rather low or inappropriately normal or minimally elevated. Consequently, simultaneous measurements of both the serum-free T_4 and TSH would be required to further substantiate or exclude this diagnosis. Central hypothyroidism can also be confirmed by assessing the serum TSH response to an injection of TRH. To perform this test, serum samples for TSH are obtained before and 30 to 60 minutes after 200 µg of TRH is administered intravenously. The absence of a significant rise in serum TSH concentration (eg, to a peak value >7 mU/L) indicates pituitary or hypothalamic disease or suppression by exogenous thyroid hormone. A modest and delayed rise may be seen in patients with

TABLE 7–4   Causes of inappropriate serum TSH concentration.[a]

Clinical Hyperthyroidism
TSH-secreting pituitary adenoma
Isolated pituitary resistance to thyroid hormone
Clinical Hypothyroidism
Central (pituitary or hypothalamic) hypothyroidism
Preceding TSH suppression (eg, recently treated hyperthyroidism)
Clinical Euthyroidism
Systemic illnesses ($\downarrow$ during acute phase, $\uparrow$ during recovery)
Generalized resistance to thyroid hormone (compensated)
Assay interference
Anti-TSH antibodies
Anti-mouse immunoglobulin antibodies
Drugs: dopamine, dobutamine, glucocorticoids
Normal effect of aging, especially age >80 years
Marked obesity

[a]"Inappropriate" refers to disruption of the usual reciprocal relationship between serum TSH and free thyroid hormone concentrations.

hypothalamic disease and tertiary hypothyroidism. Currently, TRH is not available in the United States. Another cause of a misleadingly low serum TSH concentration is drug treatment with either high-dose corticosteroids or dopamine, both of which inhibit TSH secretion (see Table 7–4).

A second limitation of TSH testing alone is that there are other nonthyroidal causes of an elevated serum TSH concentration, as described in Table 7–4.

Serum T_4 and T_3 Measurements

The concentrations of total and free (unbound) T_4 and T_3 are measurable by a variety of automated assay techniques. Serum total thyroid hormone concentrations are widely available and accurate for assessment of most patients with overt thyroid dysfunction. However, a limitation of these assays is they can provide false-positive and false-negative results when changes in the concentration or binding affinity of the thyroid hormone–binding plasma proteins are altered. For example, a pregnant woman with an estrogen-induced increase in the concentration of TBG could be misdiagnosed as being hyperthyroid if only a total T_4 assay was employed. Conversely, a pregnant patient with primary hypothyroidism might be overlooked if the elevated TBG concentration produced total T_4 within the reference range. Despite these reservations, diagnostic accuracy is high when total T_4 assay results are interpreted along with TSH assay findings.

These problems are circumvented by measuring the free thyroxine (FT_4) concentration by free T_4 IMAs, equilibrium dialysis, or liquid chromatography/mass spectrometry (LC/MS). Free T_4 assays employ strategies to measure only the unbound fraction of T_4 in serum samples. One approach is to employ a competing T_4 analog tracer that binds to the assay Ab but not to plasma proteins. Such free T_4 assays are quite accurate in distinguishing straightforward TBG derangements from true FT_4 abnormalities due to thyroid dysfunction. However, they may be influenced to some extent by variations in total T_4, and they can yield misleadingly high readings in dysalbuminemic hyperthyroxinemia and

falsely low readings in the third trimester of pregnancy. However, free T_4 IMAs are currently the most widely used method for free T_4 determination because they are accurate in most settings, rapid, automatable, and inexpensive.

Equilibrium dialysis entails equilibrating a serum sample with buffer across a membrane with pores that permit passage only of unbound T_4; then the dialysate is assayed for its T_4 concentration, from which the serum concentration can be derived. Although equilibrium dialysis is considered the gold standard for free T_4 determination, it is cumbersome, relatively expensive, and not widely available. Consequently, it is not the optimal first-line method for free T_4 measurement, and it is best reserved for special circumstances.

Free T_4 estimation by free T_4 index entails measuring the total T_4 in a conventional IMA and then estimating the partition of a tracer iodothyronine between plasma proteins and a matrix with a virtually limitless binding capacity for small molecules (resin, charcoal, or talc). Radiolabeled T_3 is often the tracer employed, although T_4 tracer can be used as well. The free T_4 index is then calculated as the product of the total T_4 multiplied by the percentage of iodothyronine tracer taken up by the matrix, the so-called T_3 uptake. It is important to note that this refers to the T_3 tracer used in the assay, not the T_3 level in the serum sample.

When the free T_4 concentration alone is used to diagnose thyroid dysfunction, there are a number of conditions from which true hyperthyroidism or hypothyroidism must be distinguished. First, there are several conditions in which euthyroid individuals can develop hyperthyroxinemia (see Table 7–1). These include rare patients with nonthyroidal illnesses; unusual plasma-binding proteins abnormalities, such as familial dysalbuminemic hyperthyroxinemia (see later); and illness or drugs that block T_4-to-T_3 conversion (eg, iodinated contrast media, amiodarone, glucocorticoids, and propranolol). In these conditions, true hyperthyroidism is excluded by the normal serum TSH level. Conversely, there are also conditions in which the serum-free T_4 can be subnormal in euthyroid individuals. Antiepileptic drugs, such as phenytoin and carbamazepine, have multiple actions that lower total and free T_4 levels, including inhibition of TSH secretion and accelerating T_4 catabolism. However, the normal accompanying serum TSH and equilibrium dialysis T_4 levels implies that these patients are, in fact, euthyroid.

Total and free T_3 concentrations can also be quantitated in specific IMAs. Measurement of serum T_3 is used (1) to recognize patients who have T_3 toxicosis, a milder degree of hyperthyroidism in which the serum T_3 level is elevated with a normal serum T_4; (2) to fully define the severity of hyperthyroidism and monitor the response to therapy; and (3) to help in the differential diagnosis of patients with hyperthyroidism. Because T_3 is preferentially secreted in most patients with Graves disease, and some with toxic nodular goiter, the ratios of serum T_3:T_4 (expressed in ng/dL:µg/dL) are typically greater than 20 in patients with these conditions. In contrast, in thyroiditis-related thyrotoxicosis the serum T_3:T_4 ratio is usually less than 20, reflecting the relative amounts of the two hormones stored in and leaking from the inflamed gland.

The serum T_3 concentration is not accurate for diagnosis of hypothyroidism because a normal T_3 level is often maintained in

TABLE 7–5 Representative iodothyronine kinetic values in a euthyroid human.

	T_4	T_3	rT_3
Serum levels			
Total, µg/dL (nmol/L)	8 (103)	0.12 (1.84)	0.04 (0.51)
Free, ng/dL (pmol/L)	1.5 (19)	0.28 (4.3)	0.24 (3.69)
Body pool, µg (nmol)	800 (1023)	46 (70.7)	40 (61.5)
Distribution volume (L)	10	38	98
Metabolic clearance rate (MCR) (L/d)	1	22	90
Production (disposal) rate MCR × serum concentration, µg/d (nmol/d)	80 (103)	26 (34)	36 (46)
Half-life in plasma ($t1/2$) (days)	7	1	0.2

Note: T_4 µg/dL × 12.87 = nmol/L; T_3 µg/dL × 15.38 = nmol/L.

FIGURE 7–25 Typical curves of 24-hour radioiodine uptake in normal subjects and in patients with thyroid disease. A high-turnover curve may be seen in patients taking an iodine-deficient diet or with a defect in hormone synthesis.

patients with mild to moderate primary hypothyroidism, in part because TSH stimulation of the thyroid gland increases the relative secretion of T_3. Because T_3 is bound to TBG, the total serum T_3 concentration varies with the TBG level, although less than the serum total T_4 (Table 7–5). Serum-free T_3 can be measured by IMA or more precisely by equilibrium dialysis.
Reverse T_3 can be measured by RIA; its serum concentration in adults is about one-third of the total T_3 concentration. However, there is little or no clinical indication for rT_3 measurement. Previous claims that it is useful to differentiate hypothyroidism from the thyroid function test changes of nonthyroidal illness have not shown that rT_3 levels are sufficiently accurate for that purpose.

TG can be measured in serum by either IMA or RIA, which now have sensitivities as low as 0.1 ng/mL. There are two indications for TG measurement: (1) detection of residual or recurrent epithelial thyroid cancers (papillary, follicular, and Hürthle cell carcinomas) after thyroidectomy (see section Management of Thyroid Cancer); and (2) differentiation of thyrotoxicosis due to exogenous thyroid hormone, in which the TG level is suppressed, from all forms of endogenous hyperthyroidism, including various forms of thyroiditis, in which it is elevated or normal.

There are several potential limitations of current TG IMAs. The most important is interference caused by the presence of circulating TG Abs. This usually leads to spuriously low values in thyroglobulin IMAs and falsely elevated values in RIAs. Serum TG levels are not useful to differentiate malignant from benign thyroid nodules.

ASSESSMENT OF THYROID IODINE METABOLISM AND BIOSYNTHETIC ACTIVITY

Radionuclide uptake measurements can be used to differentiate among the causes of thyrotoxicosis, particularly when used in conjunction with imaging. Radioiodine uptake determinations

permit *in vivo* assessment of fractional iodine uptake and turnover by the thyroid gland. Iodine-123 is the ideal isotope for this purpose, with 13-hour half-life and emitting quantifiable 28-keV x-rays and 159-keV gamma photons but no tissue damaging beta particles. [123]I—or when it is unavailable, a low dose of [131]I—is given orally, and radioactivity over the thyroid is quantified with a scintillation counter at 4 or 6 hours and again at 24 hours (Figure 7–25). The fractional radioactive iodine uptake (RAIU) by the thyroid varies with recent dietary iodide intake. In countries with a relatively high iodide intake (eg, USA, Chile, and Brazil), the normal RAIU is 5% to 15% at 6 hours and 8% to 30% at 24 hours, whereas in areas of low-iodide intake and endemic goiter (eg, some parts of Europe and sub-Saharan Africa), the 24-hour RAIU can be as high as 60% to 90%.

In hyperthyroid Graves disease, the 24-hour RAIU is markedly elevated (eg, 40%-95%), although if iodide turnover is very rapid, the 5-hour uptake may be even higher than the 24-hour uptake (see Figure 7–25). Similarly, the 24-hour RAIU is increased to a lesser extent in toxic nodular goiter (eg, 30%-70%). Thyrotoxicosis with a low-thyroidal RAIU occurs in patients with several conditions: (1) subacute and lymphocytic (postpartum, silent) thyroiditis with inflammatory release of preformed hormone causing spontaneously resolving thyrotoxicosis; (2) in iatrogenic or factitious thyrotoxicosis resulting from excessive thyroid hormone medication; and (3) following excess oral or intravenous iodide intake, as occurs, for example, with amiodarone therapy or after radiocontrast agents. There can also be low RAIU over the anterior neck when there is excessive thyroid hormone production elsewhere in the body, as occurs with ectopic thyroid tissue at the tongue base (lingual thyroid); in the mediastinum; with struma ovarii, an ovarian teratoma with functioning thyroid tissue; and with functioning metastases from thyroid carcinoma after total thyroidectomy.

THYROID IMAGING

1. RADIONUCLIDE IMAGING

[123]I and technetium ^{99m}Tc pertechnetate ([99m]TcO$_4$) are useful for determining the functional activity and morphology of the
FIGURE 7–26 **A.** Rectilinear sodium ^{123}I scan performed 6 hours after the ingestion of 100 μCi of sodium [123]I. **B.** Scintiphoto (pinhole collimator) thyroid scan performed 6 hours after the ingestion of 100 μCi of sodium [123]I. (Used with permission from Dr. RR Cavalieri.)

thyroid gland. [123]I (200-300 μCi) is administered orally, and an image of the thyroid is obtained 8 to 24 hours later. $^{99m}TcO_4$ (1-10 mCi), which is trapped by the NIS, but not organified and retained in the gland, is administered intravenously, and the scan image is obtained earlier than usual—at 30-60 minutes. Images can be obtained with either a rectilinear scanner or a gamma camera. The rectilinear scanner moves back and forth over the area of interest and produces a life-size picture, on which regions of interest, such as nodules, can be marked (Figure 7–26A). The gamma camera has a pinhole collimator, and the scan is obtained on a fluorescent screen and recorded on film or a computer monitor. The camera has greater resolution, but regions of interest must be identified with a radioactive marker for clinical correlation (Figure 7–26B).

Radionuclide scans provide information about the size and shape of the thyroid gland and the distribution of tracer activity within the gland. This is useful in differentiating among the causes of thyrotoxicosis. For example, in patients with hyperthyroidism, an enlarged gland with intense and homogenous concentration of tracer is typical of Graves disease. In contrast, one or more discrete regions of tracer activity, especially corresponding to a palpable nodule or nodules, with suppression of extranodular tissue are characteristic of toxic nodular goiter.

Radionuclide imaging has a limited role in differentiation of benign from malignant thyroid nodules. When a patient with a thyroid nodule has a suppressed serum TSH concentration, a radionuclide scan is often appropriate to determine if the nodule is *hot* (ie, functioning with suppression of extranodular thyroid tissue). If this is the case, the nodule can generally be considered benign. Because both most benign and malignant thyroid nodules are *cold*, or hypofunctioning, documenting this is not particularly helpful, and cytologic evaluation must be performed in any case.

Radionuclide whole body scanning is useful in follow-up of patients with treated thyroid cancer and for confirmation that a mass on the tongue (lingual thyroid), in the midline of the neck (thyroglossal duct), mediastinum (substernal goiter), or pelvis (struma ovarii) represents ectopic thyroid tissue.

THYROID ULTRASONOGRAPHY AND OTHER IMAGING TECHNIQUES

The size of the thyroid gland and characteristics of nodular lesions within it are best ascertained by high-resolution ultrasonography (Figure 7–27). Sonography can differentiate solid nodules from cystic lesions and characterize complex cysts that have both solid and cystic components. Certain features of nodules are more common in malignant lesions (eg, hypoechogenicity, irregular nodule capsule, and microcalcifications), and other features are typical of benign lesions (eg, iso- or hyperechogenicity, a *spongiform* appearance and cystic change). Sonography can be used to serially monitor the size of thyroid nodules over time, to guide fine-needle aspiration of thyroid nodules, and to assess regional lymph nodes in thyroid cancer patients both preoperatively and in long-term follow-up. Sonographic assessment of thyroid gland blood flow can be useful in the differential diagnosis of amiodarone-induced thyrotoxicosis.

Computed tomography (CT) and magnetic resonance imaging (MRI) are useful in patients with thyroid disease in special settings. They may be required to define the posterior cervical and substernal extent of a large goiter, and whether there is tracheal deviation or compression. In thyroid cancer patients, they can be helpful in identifying metastatic disease outside of the neck (eg, in the lungs, liver). However, it should be remembered that administration of iodine-containing radiocontrast dye for CT imaging interferes with subsequent radioiodine imaging and therapy for up to several months. Positron emission tomography (PET) scanning has a role in localization of metastatic disease in treated thyroid cancer patients who have a serum TG concentration greater than 10 ng/mL.

When any of the earlier-described techniques are used for other indications to image structures in the cervical region, thyroid nodules are commonly detected incidentally. Studies indicate that the prevalence of thyroid cancer in such thyroid incidentalomas is the same as in palpable nodules, so they should usually be biopsied if greater than 1.0 to 1.5 cm in diameter, and monitored by serial ultrasound if smaller. FDG PET incidentalomas, in particular, should be thoroughly evaluated, as some studies have shown that many of these hypermetabolic lesions have been found to be cancers.

Glands afflicted with thyroiditis can also be identified on FDG PET scanning.

THYROID BIOPSY

Fine-needle aspiration biopsy (FNAB) of a thyroid nodule to obtain material for cytopathological inspection is the best method for differentiating benign from malignant thyroid nodules and diffuse goiters. FNAB is a minor outpatient procedure performed in awake, nonfasting patients with appropriate aseptic technique; local anesthesia may or may not be required. The procedure is typically performed with a 27- or 25-gauge needle, which is inserted into the nodule or goiter, and moved in and out until a small amount of bloody material is seen in the hub of the needle. The aspirated material is then expressed onto a glass slide and prepared as a thin smear, which is either air-dried for immediate

Trans is thmus
FIGURE 7–27 *(Continued)*

staining and preliminarily assessed, or placed in fixative for definitive staining and cytopathologic assessment. FNAB can also be useful to evacuate cystic lesions, although the fluid recollects in one-half of these cysts.

Cytologic diagnosis of malignancy in thyroid nodules is highly accurate. The sensitivity for cancer detection (true-positive diagnoses divided by total number of nodules proven to be cancer by surgery) is 95% to 98%, and the specificity for cancer (true-positive results divided by total number of cases with a positive biopsy) is also 98%. Conversely, among the remaining nodules, a benign cytological finding is very reassuring with a 97% negative predictive value (true-negative results divided by all negative results). However, approximately one-third of thyroid nodules yield tissue that is cytologically indeterminate, which can be subcategorized as atypia of undetermined significance, follicular neoplasm, or suspicious for malignancy with estimated cancer risks of 5% to 15%, 15% to 30%, and 60% to 75%, respectively. These issues are discussed in depth in the section Thyroid Nodules and Thyroid Cancer.

TEST OF PERIPHERAL THYROID HORMONE ACTIONS

Theoretically, the most definitive test of thyroid function would be a method of quantifying thyroid hormone responses in peripheral tissues. In practice, however, these tests have limited accuracy because the response parameters may be imprecisely quantified (eg, ankle reflex relaxation time) or because they are also modulated by nonthyroidal factors (eg, serum cholesterol and echocardiographic systolic time intervals). Nonetheless, these techniques are useful in clinical research and in assessment of rare patients suspected of having resistance to thyroid hormone (RTH).

Basal oxygen consumption reflects thyroid hormones' effects on oxygen consumption and calorigenesis in most body tissues, especially the liver. There is considerable overlap between the measured levels in hypothyroidism, euthyroidism, and hyperthyroidism. Echocardiography can be used to assess systolic and diastolic functions, both of which are altered with thyroid dysfunction; but this is exclusively a research technique.

Thyroid hormones influence the concentrations of a number of analytes in blood. For example, serum total and LDL cholesterol is usually elevated in hypothyroidism and lowered in hyperthyroidism. In hyperthyroidism, sex hormone–binding globulin, ferritin, and angiotensin-converting enzyme concentrations are often higher, as are markers of bone formation and degradation. However, none of these test results is sensitive or specific enough for routine diagnostic use.

MEASUREMENT OF THYROID AUTOANTIBODIES

Detection of thyroid autoantibodies can be helpful in establishing the diagnosis of autoimmune thyroid disease. To establish the diagnosis of autoimmune (Hashimoto) thyroiditis in a patient with diffuse goiter or hypothyroidism, serum anti-TPO or the less sensitive anti-TG Abs can be employed. An older test, antimicrosomal Abs has intermediate sensitivity. Anti-TPO and anti-TG Abs can be measured by hemagglutination, enzyme-linked immunosorbent assay (ELISA), or RIA; RIA is more sensitive, precisely quantifiable, and generally preferred. Although these Abs are most typical of autoimmune thyroiditis, they are also detected in significant proportions of patients with Graves disease and certain other forms of thyroiditis. Due to their high prevalence in the population, especially in women, a positive result does not rule out presence of a second thyroid disorder (eg, cancer in an asymmetrical goiter).

TSH receptor–stimulating, –binding, and –blocking Abs can all be detected. TSI (also called TSAb) is present in approximately 90% of patients with Graves disease and is almost never detected in unaffected patients or those with other autoimmune thyroid diseases. The test is performed by exposing a patient's IgG to cultured Chinese hamster ovary cells that have been transfected with the TSH receptor gene and then measuring their cAMP response in comparison with control IgG and TSH standards. TSI testing is used in a few special settings: (1) pregnant women to define risk of subsequent neonatal hyperthyroidism in their fetus and neonate; (2) to differentiate Graves disease from postpartum thyroiditis in women who are breast feeding and cannot have a radionuclide thyroid uptake; (3) to make the diagnosis of Graves disease in euthyroid patients with apparent thyroid-related ophthalmopathy; and (4) to predict whether antithyroid drug-treated Graves patients will relapse when drug is later discontinued. TSH receptor–binding immunoglobulins can also be detected by *in vitro* demonstration that circulating immunoglobulins compete with radiolabeled TSH in binding to recombinant TSH receptors. It is a simpler alternative for the TSI indications described earlier, but does not distinguish between stimulating and blocking anti-TSH receptor Abs. TSH receptor blocking Abs have been implicated as the cause of hypothyroidism in a minority of hypothyroid patients in certain populations; they can also be transmitted transplacentally to the fetus and inhibit thyroid function during pregnancy and in the neonatal period.

DISORDERS OF THE THYROID

Patients with thyroid disease usually complain of one or more of the following: (1) thyroid enlargement, which may be diffuse or nodular; (2) symptoms of thyroid hormone deficiency, or hypothyroidism; (3) symptoms of thyroid hormone excess, or hyperthyroidism; or (4) complications of a specific form of hyperthyroidism—Graves disease—that may present with striking prominence of the eyes (exophthalmos) and, rarely, thickening of the skin over the lower legs (thyroid dermopathy or pretibial myxedema). Patients with thyroid nodules, whether benign or malignant, often have no symptoms, as do persons with mild perturbations of thyroid function.

History

The history should include evaluation of symptoms related to an enlarged gland, thyroid hormone deficiency and excess, as discussed in more detail later. The history should identify risk factors for thyroid disease. Exposure to ionizing radiation in childhood has been associated with an increased incidence of thyroid disease, including cancer. Iodide ingestion in the form of amiodarone, an iodine-containing antiarrhythmic drug, or intravenous iodide-containing contrast media used in angiography or CT scanning may induce hypothyroidism or hyperthyroidism. Residence in an area of low dietary iodide is associated with iodine deficiency goiter (endemic goiter). The family history should be explored with particular reference to goiter, hyperthyroidism, hypothyroidism, or thyroid cancer as well as immunologic disorders such as type 1

diabetes, pernicious anemia, alopecia, vitiligo, or myasthenia gravis, which may be associated with an increased incidence of autoimmune thyroid disease. Multiple endocrine neoplasia types 2A (Sipple syndrome) and 2B with medullary carcinoma of the thyroid gland are autosomal dominant conditions.

Physical Examination

Physical examination of the thyroid gland is illustrated in Figure 7–28. The thyroid is firmly attached to the anterior trachea midway between the sternal notch and the thyroid cartilage; it is often easy to see and to palpate. The patient should have a glass of water for comfortable swallowing. There are three maneuvers:

1. With a good light coming from behind the examiner, the patient is instructed to swallow a sip of water. Observe the gland as it moves up and down. Enlargement and nodularity can often be noted.
2. Palpate the gland anteriorly with swallowing. The thumb placed anteriorly along the trachea allows localization of the isthmus and connected lobes, and if present the pyramidal lobe, which extends superiorly from the isthmus and is often palpable in patients with autoimmune thyroid disease.
3. Then, the examiner's right hand is placed on the patient's left shoulder, and the examiner's right thumb is used to palpate the left lobe, as the patient swallows. This permits a full appreciation of the size, texture, and contour of the lobe. Then, using the left hand, the right lobe can be palpated. The examiner's thumbs should be medial to the sternocleidomastoid muscles to avoid mistaking them for the thyroid lobes. Some experts recommend palpation from behind using three fingers to palpate each lobe while the patient swallows, but this technique has the disadvantage of not being able to see the gland during palpation.

Normally, the thyroid is just barely palpable, has a smooth surface, and has a soft to rubbery consistency. The palpable bulbous portion of each lobe of the normal thyroid gland measures about 2 cm in vertical dimension and about 1 cm in horizontal dimension above the isthmus. An enlarged thyroid gland is called a **goiter**. Generalized enlargement is termed **diffuse goiter**; irregular or lumpy enlargement is called **nodular goiter**. In Hashimoto thyroiditis, the gland is often symmetrically enlarged, firm, and has a bosselated (cobblestone) or finely nodular surface. In the atrophic form of Hashimoto thyroiditis, the gland may not be palpable at all. In patients with Graves disease, the gland is usually, but not always, symmetrically enlarged, smooth, and rubbery in consistency. Multinodular goiters have one or more distinct nodules palpable, although both small and large and nodules may not be palpable because of their location or consistency. Tenderness of the gland should be noted. In patients with Graves disease, the presence of a bruit by auscultation should be sought, and a thrill may be palpable over the gland. Tracheal deviation by a goiter, cervical lymphadenopathy possibly related to thyroid cancer, and jugular venous distention and facial erythema from thoracic inlet obstruction by a large goiter should be noted as well. An outline of the gland can be traced on the skin of the neck and measured (Figure 7–28D). Nodules can be measured in a similar way. Thus, changes in the size of the gland or in nodules can easily be followed.
FIGURE 7–28 Examination of the thyroid gland. **A.** Observe the neck, especially as the patient swallows. **B.** Examine from the front, rotating the gland slightly with one thumb while palpating the other lobe with the other thumb. **C.** Examine from behind, using three fingers and the same technique. **D.** The size of each lobe or of thyroid nodules can be measured by first drawing an outline on the skin.

HYPOTHYROIDISM

Hypothyroidism is a clinical syndrome resulting from a deficiency of thyroid hormones, which results in widespread organ-specific effects. Hypothyroidism in infants and children results in marked slowing of growth and development, with serious permanent consequences, including mental retardation when it occurs in infancy and short stature, when it occurs in later childhood. Hypothyroidism with onset in adulthood causes diminished calorigenesis and oxygen consumption; impaired cardiac, pulmonary, renal, gastrointestinal, and neurological functions and deposition of glycosaminoglycans in intracellular spaces, particularly in skin and muscle, producing in extreme cases the clinical picture of **myxedema**. The symptoms and signs of hypothyroidism in adults (described in detail later) are reversible with therapy.

Etiology and Incidence (Table 7–6)

Hypothyroidism may be classified as (1) *primary* which is by far the most common, (2) *secondary* due to pituitary TSH deficiency, (3) *tertiary* due to hypothalamic TRH deficiency, or (4) *peripheral thyroid hormone resistance*.

The incidence of various causes of hypothyroidism varies depending on geographic and environmental factors, such as

TABLE 7–6 Etiology of hypothyroidism.

Primary:
1. Hashimoto thyroiditis:
    a. With goiter
    b. "Idiopathic" thyroid atrophy, presumably end-stage autoimmune thyroid disease, following either Hashimoto thyroiditis or Graves disease
    c. Neonatal hypothyroidism due to placental transmission of TSH-R blocking antibodies
2. Radioactive iodine therapy for Graves disease
3. Subtotal thyroidectomy for Graves disease, nodular goiter, or thyroid cancer
4. Excessive iodide intake (kelp, radiocontrast dyes)
5. Subacute thyroiditis (usually transient)
6. Iodide deficiency (rare in North America)
7. Inborn errors of thyroid hormone synthesis
8. Drugs
    a. Lithium
    b. Interferon-alfa
    c. Amiodarone

Secondary: Hypopituitarism due to pituitary adenoma, pituitary ablative therapy, or pituitary destruction

Tertiary: Hypothalamic dysfunction (rare)

Peripheral resistance to the action of thyroid hormone

dietary iodide and goitrogen intake, the genetic characteristics of the population, and the age distribution of the population (pediatric or adult). Iodine deficiency is is still frequently seen in developing countries and is the most common cause of hypothyroidism world wide. The causes of hypothyroidism, listed in approximate order of frequency in the United States, are presented in Table 7–6. Hashimoto thyroiditis is by far the most common cause of hypothyroidism in the developed world. In younger patients, it is more likely to be associated with goiter; in older patients, the gland may be totally destroyed by the immunologic process, and the only trace of the disease is a persistently positive test for TPO Abs. Similarly, the end stage of Graves disease may be hypothyroidism, occurring spontaneously or following destructive therapy with radioactive iodine or thyroidectomy. Thyroid glands afflicted with autoimmune inflammation are particularly susceptible to excessive iodide intake (eg, ingestion of kelp tablets, iodide-containing cough preparations, or the antiarrhythmic drug amiodarone) or intravenous administration of iodide-containing radiographic contrast media. Large amounts of iodide block thyroid hormone synthesis via the Wolff-Chaikoff effect (see earlier), producing iodine-induced hypothyroidism with goiter in the patient with an abnormal thyroid gland; the normal gland *escapes* from the Wolff-Chaikoff effect or iodide block, but for unclear reasons, autoimmunity renders the gland more sensitive to the inhibitory effects of iodine. Hypothyroidism may occur during the late phase of subacute thyroiditis or silent thyroiditis; this is usually transient, but it may be permanent especially in silent thyroiditis, where permanent hypothyroidism occurs in about 25% of patients. Certain drugs can block hormone synthesis and produce hypothyroidism with goiter; at present, the most common pharmacologic causes of hypothyroidism (other than iodide) are lithium carbonate, used for the treatment of bipolar disease, and amiodarone. Chronic therapy of hyperthyroidism with the antithyroid drugs PTU and methimazole have the same effects. Interferon alfa, used infrequently now to treat hepatitis C and other conditions, can cause altered immunity that can result in hypothyroidism due to Hashimoto thyroiditis. Inborn errors of thyroid hormone synthesis, called thyroid dyshormonogenesis, result from genetic deficiencies in enzymes necessary for hormone biosynthesis. These effects may be complete, resulting in a syndrome of severe congenital hypothyroidism (cretinism) with goiter; or partial, resulting in goiter with milder hypothyroidism. At least five separate biosynthetic abnormalities have been reported: (1) impaired transport of iodine; (2) deficient TPO with impaired oxidation of iodide to iodine and failure to incorporate iodine into TG; (3) impaired coupling of iodinated tyrosines to triiodothyronine or tetraiodothyronine; (4) absence or deficiency of iodotyrosine deiodinase, so that iodine is not conserved within the gland; and (5) excessive production of metabolically inactive iodoprotein by the thyroid gland (see Figure 7–6). The latter may involve impaired or abnormal TG synthesis.

Pituitary and hypothalamic deficiencies as causes of hypothyroidism are quite rare and are usually associated with other symptoms and signs of pituitary insufficiency (see Chapter 4). Peripheral RTH is discussed later.

Pathogenesis

Thyroid hormone deficiency affects virtually every tissue in the body, so that the symptoms are multiple. Pathologically, the most characteristic finding is the accumulation of glycosaminoglycans—mostly hyaluronic acid—in interstitial tissues. Accumulation of this hydrophilic substance and increased capillary permeability to albumin account for the interstitial nonpitting edema that is particularly evident in the skin, heart muscle, and striated muscle. The accumulation is due not to excessive synthesis but to decreased metabolism of glycosaminoglycans.

Clinical Presentations and Findings

A. Newborn infants (cretinism) The term cretinism was originally applied to infants born in areas of severe iodine deficiency with mental retardation, short stature, a characteristic puffy appearance of the face and hands, and (frequently) deaf mutism and neurologic signs of pyramidal and extrapyramidal tract abnormalities. In the United States, neonatal screening programs have revealed that in the Caucasian population the prevalence of sporadic neonatal hypothyroidism is 1:5000, whereas in the African American population the prevalence is only 1:32,000. In areas of iodine sufficiency, neonatal hypothyroidism typically results from failure of the thyroid to descend during embryonic development from its origin at the base of the tongue to its usual site in the lower anterior neck, resulting in an absent or *ectopic thyroid* gland that functions poorly. Placental transfer to the embryo of blocking anti-TSH receptor Abs from a mother with Hashimoto thyroiditis may result in agenesis of the thyroid gland and athyreotic cretinism, but usually it only causes transient hypothyroidism. Inherited defects in thyroid hormone biosynthesis may also cause neonatal hypothyroidism and goiter. Other possible causes of neonatal hypothyroidism include exposure during pregnancy to iodides, antithyroid drugs given to the mother, or inadvertent administration of radioactive iodine for thyrotoxicosis or thyroid cancer.

The signs of hypothyroidism in newborns include respiratory difficulty, cyanosis, jaundice, poor feeding, hoarse cry, umbilical hernia, and marked retardation of bone maturation. The proximal tibial epiphysis and distal femoral epiphysis are present in almost all full-term infants with a body weight over 2500 g. Absence of these epiphyses strongly suggests hypothyroidism. The introduction of routine screening of newborns for TSH or T_4 in the developed world has been a major public health achievement, because early diagnosis can prevent permanent mental retardation. A drop of blood obtained by heel stick 24 to 48 hours after birth is placed on filter paper and sent to a central laboratory. A serum T_4 under 6 µg/dL or a serum TSH over 25 mU/L is suggestive of neonatal hypothyroidism. The diagnosis can then be confirmed by repeat testing and radiologic evidence of retarded bone age. Note that euthyroid infants born to hypothyroid mothers who have been inadequately treated with levothyroxine during pregnancy are not hypothyroid, but may have diminished intellectual potential later in childhood—emphasizing the importance of maintaining the mother in a euthyroid state throughout pregnancy.

B. Children and adolescents   Hypothyroidism in children and adolescents is characterized by retarded growth and short stature, the typical signs and symptoms of hypothyroidism seen in adults (see later), and variable but usually declining school performance. Precocious puberty may occur, and there may be enlargement of the sella turcica due to pituitary thyrotrope hyperplasia associated with augmented TSH production.

C. Adults   In adults, the common features of moderate to severe hypothyroidism include easy fatigability; cold sensitivity; weight gain (generally <10-20 lb); constipation; menstrual abnormalities, especially menorrhagia; and muscle cramps. Physical findings may include a cool, rough, dry skin; puffy face and hands; a hoarse, husky voice; and slow reflexes. Reduced

conversion of carotene to vitamin A and increased blood levels of carotene may give the skin a yellowish color. However, many or all of the symptoms and signs are diminished or absent in patients with milder degrees of thyroid failure.

1. **Cardiovascular signs**—Hypothyroidism is manifested by impaired ventricular contraction, bradycardia, and increased peripheral resistance, resulting in diminished cardiac output. The electrocardiogram (ECG) may reveal low voltage of QRS complexes and P and T waves, with improvement in response to therapy. Cardiac enlargement may occur, due in part to interstitial edema, nonspecific myofibrillary swelling, and left ventricular dilation, as well as nonhemodynamically significant pericardial effusion (Figure 7–29). The degree of pericardial

effusion can easily be determined by echocardiography. Although cardiac output is reduced, congestive heart failure and pulmonary edema are rarely noted. There is controversy about whether hypothyroidism induces coronary artery disease, but coronary artery disease is more common in patients with hypothyroidism, likely related to increased levels of total cholesterol, LDL cholesterol, and possibly other nontraditional atherogenic factors such as lipoprotein A and homocysteine. In patients with angina pectoris, hypothyroidism may protect the heart from ischemic stress, and replacement therapy may aggravate the angina by increasing myocardial oxygen consumption.

2. **Pulmonary function**—In the adult, hypothyroidism is characterized by shallow, slow respirations and impaired ventilatory responses to hypercapnia or hypoxia. Respiratory failure is a major problem in patients with myxedema coma (see later).

3. **Intestinal peristalsis**—Peristalsis is markedly slowed, resulting in chronic constipation and occasionally severe fecal impaction or ileus.

4. **Renal function**—Renal function is impaired, with decreased glomerular filtration rate and impaired ability to excrete a water load. This predisposes the hypothyroid patient to hyponatremia from water intoxication if excessive free water is administered.

5. **Anemia**—There are at least four mechanisms that may contribute to anemia in patients with hypothyroidism: (1) impaired hemoglobin synthesis as a result of T_4 deficiency; (2) iron deficiency from increased iron loss with menorrhagia, as well as impaired intestinal absorption of iron; (3) folate deficiency from impaired intestinal absorption of folic acid; and (4) pernicious anemia, with vitamin B_{12}-deficient megaloblastic anemia. Pernicious anemia is often part of a cluster of autoimmune diseases, including hypothyroidism due to Hashimoto or autoimmune thyroiditis associated with thyroid autoantibodies, pernicious anemia associated with parietal cell autoantibodies, diabetes mellitus associated with islet cell autoantibodies, and adrenal insufficiency associated with adrenal autoantibodies (Schmidt syndrome; see Chapter 2). These conditions are part of what has been termed the **polyendocrine failure syndrome**.

6. **Neuromuscular system**—Many patients complain of symptoms referable to the neuromuscular system, including severe muscle cramps, paresthesias, and muscle weakness.

7. **Central nervous system**—Symptoms may include chronic fatigue, lethargy, and inability to concentrate. Patients with hypothyroidism are usually quite placid but can be severely depressed or even extremely agitated (myxedema madness).

8. **Reproductive system**—Hypothyroidism impairs the conversion of estrogen precursors to estrogens resulting in altered FSH and LH secretion and in anovulatory cycles and infertility. This may be associated with menorrhagia, which may also be due, in part, to altered platelet function. Men may have decreased libido and erectile dysfunction.

Diagnosis

The combination of a low serum FT_4 and an elevated serum TSH is diagnostic of primary hypothyroidism (Figure 7–30). Serum T_3 levels are variable and may be within the normal range. Commonly, the serum FT_4 is normal or low-normal, and the serum TSH is elevated slightly, a situation termed **subclinical hypothyroidism**. This represents the mildest form of hypothyroidism and is a consequence of the very sensitive feedback relationship between the thyroid and the pituitary gland. In this situation, a small decrement in thyroid hormone output by the thyroid gland, in which serum T_4 levels are still within the normal range, results in a serum TSH level that is elevated, albeit usually less than 10 mU/L. Subclinical hypothyroidism is usually due to underlying Hashimoto thyroiditis, which can be confirmed by assessing anti-TPO Ab titers. In patients with secondary or central hypothyroidism, the serum FT_4 will be low and serum TSH will be low or normal, rather than elevated. Since serum TSH rises with advancing age, some healthy elderly persons may have mildly elevated serum TSH (eg, 5-7 mU/L), that can mimic subclinical hypothyroidism.

The patient may be taking thyroid hormone when first seen. A palpable or enlarged thyroid gland and a positive test for thyroid autoantibodies would suggest underlying Hashimoto thyroiditis, in which case the medication should be continued. If antithyroid Abs are absent and the indication for therapy uncertain, the medication could be withdrawn for 6 weeks and determination made for FT_4 and TSH. The 6-week period of withdrawal is necessary because of the long half-life of T_4 (7 days) and to allow the pituitary gland to recover after a long period of suppression. The pattern of recovery of thyroid function after withdrawal of T_4 is noted in Figure 7–31. In hypothyroid individuals, serum TSH becomes elevated at 5 to 6 weeks and FT_4 remains subnormal, whereas both are normal after 6 weeks in euthyroid individuals.

The clinical picture of fully developed myxedema is usually quite clear, but the symptoms and signs of mild or subclinical
FIGURE 7–30 Diagnosis of hypothyroidism.

FIGURE 7–31 Changes in T_4, T_3, TSH, and TRH response following abrupt withdrawal of suppressive thyroxine therapy. Note that in euthyroid individuals, the T_4 may not return to normal until 6 weeks after withdrawal of therapy and that serum TSH is never elevated. In hypothyroid patients, TSH may be elevated as early as 2 weeks after withdrawal of therapy, and TRH response is exaggerated. (LLN, lower limit of normal; ULN, upper limit of normal.) (Adapted with permission from Vagenakis AG, Braverman LE, Azizi F, et al. Recovery of pituitary thyrotropic function after withdrawal of prolonged thyroid suppression therapy. *N Engl J Med*. 1975 Oct 2;293(14):681-684.)

hypothyroidism may be very subtle or absent. This has led to the recommendation by some professional organizations that screening for hypothyroidism be undertaken, especially in high-risk groups, such as older women where the prevalence is high (up to 20% in women age >65), and in pregnant women, where untreated hypothyroidism may cause adverse outcomes in the child.

At times, patients with hypothyroidism present with unusual features: neurasthenia with symptoms of muscle cramps, paresthesias, and weakness; refractory anemia; disturbances in

reproductive function, including infertility, delayed or precocious puberty, or menorrhagia; idiopathic edema or pleuropericardial effusions; retarded growth; obstipation; chronic rhinitis or hoarseness due to edema of nasal mucosa or vocal cords; and severe depression progressing to emotional instability or even frank paranoid psychosis. In the elderly, hypothyroidism may present with apathy and withdrawal, often attributed to senility. In such cases, assessing thyroid function with serum FT_4 and TSH measurements confirms or rules out hypothyroidism as a contributing factor.

Complications

A. Myxedema coma   Myxedema coma, an extremely rare condition, is the end stage of untreated hypothyroidism (see also Chapter 24). It is characterized by progressive weakness, stupor, hypothermia, hypoventilation, hypoglycemia, and hyponatremia, and it may ultimately result in shock and death. It occurs most frequently in the winter in older female patients with underlying pulmonary and vascular disease, and the mortality rate may be greater than 50%.

The patient (or a family member if the patient is comatose) may recall previous thyroid disease, radioiodine or radiation therapy to the neck area, or thyroidectomy. The medical history is one of gradual onset of lethargy progressing to stupor or coma. Examination reveals bradycardia and marked hypothermia, with body temperature as low as 24°C (75°F). The patient is usually an obese elderly woman with yellowish skin, a hoarse voice, a large tongue, thin hair, puffy eyes, ileus, and slow reflexes. There may be signs of other illnesses such as pneumonia, myocardial infarction, cerebral thrombosis, or gastrointestinal bleeding. Seizures, bleeding episodes, hypocalcemia, or hypercalcemia may occur. Laboratory clues to the diagnosis of myxedema coma include lactescent serum, high serum carotene, hyponatremia, elevated BUN and creatinine, elevated serum cholesterol, and increased cerebrospinal fluid protein. Pleural, pericardial, or abdominal effusions with high protein content may be present. Serum tests reveal a low FT_4 and a markedly elevated TSH. Thyroid autoantibodies are usually strongly positive, indicating underlying Hashimoto thyroiditis. The ECG shows sinus bradycardia and low voltage. If laboratory studies are not immediately available, which is frequently the case, the diagnosis must be made clinically.

The pathophysiology of myxedema coma involves three major features: (1) CO_2 retention and hypoxia, (2) fluid and electrolyte imbalance, and (3) hypothermia. CO_2 retention and hypoxia are probably due in large part to a marked depression in the ventilatory responses to hypoxia and hypercapnia, although factors such as obesity, heart failure, ileus, immobilization, pneumonia, pleural or peritoneal effusions, central nervous system depression, and weak chest muscles may also contribute. Impairment of ventilatory drive is often severe, and assisted respiration is almost always necessary in patients with myxedema coma. Thyroid hormone therapy in patients with myxedema corrects the hypothermia and improves the ventilatory response to hypoxia. Water intoxication, due to reduced renal perfusion and impaired free water clearance, is the major fluid and electrolyte disturbance. This causes

hyponatremia and is best managed by free water restriction. Hypothermia may not be recognized if the ordinary clinical thermometer only goes down to about 34°C (93°F); and a thermometer that registers a broader scale must be used to obtain accurate body temperature readings. Active rewarming of the body is contraindicated, because it may induce vasodilation and vascular collapse. A rise in body temperature is a useful indication of therapeutic effectiveness of T_4 therapy.

Disorders that may precipitate myxedema coma include heart failure, pneumonia, or administration of sedative or narcotic drugs to a patient with severe hypothyroidism. Adrenal insufficiency may occur occasionally in association with myxedema coma, either due to functional pituitary impairment or concurrent autoimmune adrenal insufficiency (Schmidt syndrome). Concomitant glucocorticoid therapy is recommended until normal adrenal function can be documented by laboratory testing. It is important to differentiate myxedema coma due to primary thyroid gland failure from that due to pituitary failure (central hypothyroidism). In the latter situation, glucocorticoid replacement is essential. Clinical clues to the presence of pituitary disease include the following: a history of amenorrhea or impotence, scanty pubic or axillary hair, and normal serum cholesterol and normal or low serum TSH levels. CT or MRI may reveal an enlarged sella turcica. The treatment of myxedema coma is discussed later.

B. Hypothyroidism and heart disease   In the past, treatment of patients with severe hypothyroidism and heart disease, particularly coronary artery disease, was very difficult, because levothyroxine replacement was sometimes associated with exacerbation of angina, heart failure, or myocardial infarction. Now that β-adrenergic–blocking agents, coronary stenting, and coronary artery bypass surgery are available, hypothyroid patients with coronary artery disease can be treated medically or surgically first, and T_4 replacement therapy is then better tolerated.

C. Hypothyroidism and neuropsychiatric disease
Hypothyroidism is often associated with depression, which may be quite severe. More rarely, severely hypothyroid patients may become confused, paranoid, or even manic (myxedema madness). Screening of psychiatric admissions with serum FT_4 and TSH is an efficient way to identify these patients, who frequently respond to T_4 therapy alone or in combination with psychopharmacologic agents. The effectiveness of T_4 therapy in depressed hypothyroid patients has given rise to the hypothesis that the addition of T_3 or T_4 to psychotherapeutic regimens for depression may be helpful in patients without demonstrable thyroid disease, but this concept has been difficult to prove.

Treatment

A. Treatment of hypothyroidism   Hypothyroidism is treated with T_4, which is available in pure form and is stable and inexpensive. Because T_4 is converted to T_3 in peripheral tissues, both hormones become available, even though only one is administered. Desiccated thyroid is now considered obsolete because it

contains both T_4 and T_3, and triiodothyronine (as liothyronine) is unsatisfactory because of its rapid absorption, short half-life, and transient effects. The half-life of T_4 is about 7 days, so it needs to be given only once daily. It is well absorbed, and blood levels are easily monitored by following FT_4 and serum TSH levels. T_4 and T_3 levels are stable throughout the day, although there is a slight increase in free T_4 levels several hours after the medication is taken; this is not clinically significant.

B. Dosage of levothyroxine   Replacement doses of T_4 in adults range from 0.05 to 0.2 mg/d, with a mean of about 0.125 mg/d. The dose of T_4 varies according to the patient's age and body weight (Table 7–7). Because of more rapid T_4 metabolism, infants and young children require a surprisingly high dose of T_4 compared with adults. In adults, the mean replacement dose of T_4 is about 1.7 μg/kg/d, or about 0.8 μg/lb/d. In older adults, the replacement dose is usually lower, about 1.6 μg/kg/d, or about 0.7 μg/lb/d. For TSH suppression in patients postthyroidectomy for thyroid cancer, the average dose of T_4 is about 2.2 μg/kg/d (1 μg/lb/d). In most patients with hypothyroidism, one can begin treatment with the full estimated dose requirement. After 4 to 6 weeks, the final dose is adjusted based on the serum TSH level. The goal is to normalize the serum TSH, which is typically between 0.5 and 4 mU/L. In older patients or patients with underlying heart disease, it is best to start with a low dose of T_4 (eg, 0.025 mg/d) and increase the dose at 4- to 6-week intervals based on serum TSH measurements. Malabsorptive states or concurrent administration of soy products, aluminum hydroxide antacids, bile acid–binding resins such as cholestyramine and colestipol, calcium supplements, sucralfate, or iron compounds decrease T_4 absorption. In these patients, T_4 should be given before breakfast, when the stomach is empty, and the other compounds taken 4 hours later. Other drugs, such as the antiseizure medication carbamazepine, may increase thyroid hormone requirements by increasing T_4 metabolism. Proton pump inhibitors such as omeprazole may also impair T_4 absorption, possibly because gastric acid is needed for dissolution of the tablets. Estrogen replacement may increase T_4 requirements by increased binding of free T_4 to TBG. T_4 has a sufficiently long half-life (7 days), so that if the patient is unable

TABLE 7–7 Replacement doses of levothyroxine.

Age	Dose of Levothyroxine (μg/kg/d)
0-6 mo	10-15
7-11 mo	6-8
1-5 y	5-6
6-10 y	4-5
11-20 y	1-3
Adult	1-2

to take medications by mouth for a few days, omitting T_4 therapy will not be detrimental. If a hospitalized patient is being managed by sustained parenteral therapy, the parenteral dose of T_4 is about 75% to 80% of the usual oral dose.

C. Treatment of myxedema coma   Myxedema coma is an acute medical emergency and should be treated in the intensive care unit. Blood gases must be monitored regularly, and the patient usually requires intubation and mechanical ventilation. Associated illnesses such as infections or heart failure must be sought and appropriately treated. Intravenous fluids should be administered with caution, and excessive free water intake must be avoided. Because patients with myxedema coma may absorb drugs poorly, it is imperative to give T_4 intravenously. These patients have marked total body depletion, and they should receive an initial loading dose of 300 to 400 μg of T_4 intravenously followed by 80% of the calculated full replacement dose intravenously daily. Management of patients with known or suspected heart disease is described later. If, after a few days, the clinical response has been suboptimal, some experts recommend adding intravenous T_3 to the regimen at a dose of 5 μg every 6 hours. The clinical guides to improvement are a rise in body temperature and the return of normal cerebral and respiratory function. The possibility of concomitant adrenal insufficiency (due to autoimmune adrenal disease or pituitary insufficiency) needs to be considered and ruled out with a cosyntropin stimulation test (see Chapter 9). Full adrenal support should then be administered (eg, hydrocortisone hemisuccinate) 100 mg intravenously, followed by 50 mg intravenously every 6 hours, tapering the dose over 7 days. Adrenal support can be withdrawn if the pretreatment plasma cortisol is 20 μg/dL or greater or if results of a cosyntropin stimulation test are within normal limits. When giving T_4 intravenously in large doses, there is an inherent risk of precipitating angina, heart failure, or arrhythmias in older patients with underlying coronary artery disease.

At one time, the mortality rate of myxedema coma was about 80%. The prognosis has been vastly improved as a result of recognition of the importance of mechanically assisted ventilation and the use of intravenous T_4. At present, the outcome probably depends on how well the underlying comorbidities and consequences of severe hypothyroidism can be managed.

D. Severe hypothyroidism with heart disease   In older patients—particularly those with known cardiovascular disease—it is wise to start treatment slowly. T_4 is given in a dosage of 0.025 mg/d for 2 to 4 weeks, increasing by 0.025 mg every 2 to 4 weeks until a daily dose of 0.075 mg is reached. This dose is continued for about 6 weeks. Serum TSH is then measured and the dosage adjusted accordingly. It typically takes 2 to 4 months for a patient to come into equilibrium on full dosage. In some patients, the heart is very sensitive to the level of circulating T_4, and if angina pectoris or cardiac arrhythmia develops, it is essential to reduce the dose of T_4 immediately.

Adverse Effects of T_4 Therapy

There are no reported instances of allergy to pure T_4, although it is possible that a patient may develop an allergy to the coloring dye or some component of the tablet. The major toxic effects of T_4 overdosage are symptoms and signs of hyperthyroidism. Palpitations are the most common thyrotoxic cardiac symptom, and arrhythmias, particularly paroxysmal atrial tachycardia or atrial fibrillation, may occur. Insomnia, tremor, restlessness, and excessive warmth may also be troublesome. Simply omitting the daily dose of T_4 for 3 days and then reducing the dosage will correct the problem.

Increased bone resorption and osteoporosis have been associated with longstanding hyperthyroidism and will also develop in postmenopausal women chronically overtreated with T_4. This can be prevented by regular monitoring and by maintaining normal serum TSH levels in patients receiving long-term replacement therapy. In patients receiving TSH-suppressive therapy for thyroid cancer, if serum FT_4 levels are kept in the upper range of normal—even if TSH is suppressed—the adverse effects of T_4 therapy on bone will be minimal. In addition, concomitant administration of estrogen or bisphosphonates to postmenopausal women receiving high-dose T_4 therapy minimizes bone resorption.

Course and Prognosis

The course of untreated hypothyroidism is one of slow deterioration, potentially leading eventually to myxedema coma and death. With appropriate treatment, however, the long-term prognosis is excellent. Because of the long half-life (7 days) of T_4, it takes time to establish equilibrium on a fixed dose. Therefore, it is important to monitor the serum FT_4 and TSH every 4 to 6 weeks until equilibrium is reached. Thereafter, FT_4 and TSH can be monitored once in every 6 to 12 months. The dose of T_4 is increased by about 50% in most women during pregnancy with the greatest dosage increases in those women with the least thyroid reserve (ie, in women who have had a thyroidectomy or who have received radioactive iodine therapy). Older patients metabolize T_4 more slowly, and the dose likely gradually decreases with age. A small proportion of patients with hypothyroidism treated with levothyroxine monotherapy continue to have symptoms consistent with thyroid hormone deficiency, despite having normal serum FT_4 and TSH levels. The cause of this phenomenon is not known, but some experts have recommended a trial of combination T_4 and T_3 therapy in selected patients, despite the fact that controlled trials that have compared T_4 monotherapy to T_4 plus T_3 combination therapy showed no apparent benefit.

HYPERTHYROIDISM AND THYROTOXICOSIS

Thyrotoxicosis is the clinical syndrome that results when tissues are exposed to high levels of circulating thyroid hormones. It results in a generalized acceleration of metabolic processes. In most instances, thyrotoxicosis is due to hyperactivity of the thyroid gland, or hyperthyroidism. Occasionally, thyrotoxicosis may be due to other

TABLE 7–8 Conditions associated with thyrotoxicosis.

1. Diffuse toxic goiter (Graves disease)
2. Toxic adenoma (Plummer disease)
3. Toxic multinodular goiter
4. Subacute thyroiditis
5. "Silent" thyroiditis
6. Thyrotoxicosis factitia
7. Rare forms of thyrotoxicosis: ovarian struma, metastatic thyroid carcinoma (follicular), hydatidiform mole, hamburger thyrotoxicosis TSH-secreting pituitary tumor, pituitary resistance to T_3 and T_4

causes such as excessive ingestion of thyroid hormone or, very rarely, excessive secretion of thyroid hormones from an ovarian tumor (struma ovarii). Some experts reserve the term "thyrotoxicosis" for all conditions in which serum levels of thyroid hormones are elevated, while the word "hyperthyroidism" is reserved for those conditions in which the thyroid gland is synthesizing and secreting excessive quantities of thyroid hormones. Thus, Graves disease, toxic multinodular goiter, and TSH-secreting tumor are examples of "hyperthyroidism," while thyroiditis and factitious thyrotoxicosis are examples of thyrotoxicosis, but not true "hyperthyroidism." The various forms of thyrotoxicosis are listed in Table 7–8. These syndromes will be discussed individually later.

1. DIFFUSE TOXIC GOITER (GRAVES DISEASE)

Graves disease is the most common form of thyrotoxicosis. Females are involved about 5 times more commonly than males. The disease may occur at any age, with a peak incidence in the 20- to 40-year age group (see section Thyroid Autoimmunity, earlier). The syndrome consists of one or more of the following features: (1) thyrotoxicosis, (2) goiter, (3) ophthalmopathy (exophthalmos), and (4) dermopathy (pretibial myxedema).

Etiology

Graves disease is currently viewed as an autoimmune disease of unknown cause. There is a strong familial predisposition, in that about 15% of patients with Graves disease have a close relative with the same disorder, and about 50% of relatives of patients with Graves disease have circulating thyroid autoantibodies. There is a much higher concordance of Graves disease in monozygotic twins compared to dizygotic twins, but because the concordance rate in monozygotic twins is far less than 100%, there must be environmental factors that come into play as well. Proposed environmental triggers include stress, tobacco use, infection, and iodine exposure. The postpartum state, which may be associated with heightened immune function, also may trigger the development of Graves disease in genetically susceptible women.

Pathogenesis

In Graves disease, T lymphocytes become sensitized to antigens within the thyroid gland and stimulate B lymphocytes

FIGURE 7–32 One theory of the pathogenesis of Graves disease. There is a defect in suppressor T lymphocytes (T_s) that allows helper T lymphocytes (T_H) to stimulate B lymphocytes (B) to synthesize thyroid autoantibodies. The thyroid-stimulating immunoglobulin (TSI) is the driving force for thyrotoxicosis. The inflammatory process in the orbital muscles may be due to sensitization of cytotoxic T lymphocytes (T_c), or killer cells, to orbital antigens in association with cytotoxic antibodies. The thyroid and the eye are linked by a common antigen, the TSH-R, found in thyroid follicular cells and orbital fibroblasts. It is not yet clear what triggers this immunologic cascade. (Tg Ab, thyroglobulin antibody; TPO Ab, thyroperoxidase or microsomal antibody; Ag, antigen; Ab, antibody.)

to synthesize Abs to these antigens (see Chapter 2; see also the section Thyroid Autoimmunity earlier and Figure 7–32). One such Ab is directed against the TSH receptor in the thyroid cell membrane, stimulating thyroid gland growth and function. The Ab is called a thyroid-stimulating Ab (TSAb), or TSI. The presence of this circulating Ab is positively correlated with active disease and with relapse of the disease following therapy with antithyroid drugs. There is an underlying genetic predisposition, but it is not clear what triggers the initial onset of hyperthyroidism. Some factors that may incite the immune response of Graves disease are (1) pregnancy, particularly the postpartum period; (2) iodide excess, particularly in geographic areas of iodide deficiency, where the lack of iodide may hold latent Graves disease in check; (3) interferon alfa, perhaps by modifying immune responsiveness; (4) viral or bacterial infections; and (5) psychological stress. The pathogenesis of ophthalmopathy may involve cytotoxic lymphocytes (killer cells) and cytotoxic Abs sensitized to a common antigen such as the TSH receptor that is found in orbital fibroblasts, orbital muscle, and thyroid tissue (see Figure 7–32). Cytokines from these sensitized lymphocytes may cause activation and proliferation of orbital fibroblasts and preadipocytes, resulting in

FIGURE 7–33 Dermopathy of Graves disease. Marked thickening of the skin is noted, usually over the pretibial area. Thickening occasionally extends downward over the ankle and the dorsal aspect of the foot but almost never above the knee.

increased amounts of retro-orbital fat and glycosaminoglycans, as well as swollen extraocular muscles; this results in proptosis (protrusion) of the globes and diplopia, as well as redness, congestion, and conjunctival and periorbital edema (thyroid-associated ophthalmopathy or orbitopathy). For unclear reasons, smoking cigarettes is a potent risk factor for the development of thyroid-associated ophthalmopathy, possibly related to effects of tobacco smoke on orbital adipogenesis.

The pathogenesis of thyroid dermopathy (pretibial myxedema) (Figure 7–33) and the rare subperiosteal inflammation on the phalanges of the hands and feet (thyroid osteopathy or acropachy) (Figure 7–34) may also involve lymphocyte cytokine stimulation of fibroblasts in these locations. Many symptoms of thyrotoxicosis suggest a state of catecholamine excess, including tachycardia, tremor, sweating, lid lag, and stare. However, circulating levels of epinephrine and norepinephrine are normal or low; thus, in Graves disease, the body appears to have an increased sensitivity to catecholamines. This may be due in part to a thyroid hormone–mediated increase in membrane-bound β-adrenergic receptors in various tissues.

Clinical Features

A. Symptoms and signs   In younger individuals, common manifestations include palpitations, nervousness, easy fatigability, hyperkinesia, diarrhea, excessive sweating, intolerance to heat, and preference for cold. There is often marked weight loss without loss of appetite. Thyroid enlargement, thyrotoxic eye

FIGURE 7–34 Radiograph of hand of a patient with thyroid osteopathy. Note marked periosteal thickening of the proximal phalanges.

signs (see later), and mild tachycardia commonly occur. Muscle weakness and loss of muscle mass may be so severe that the patient cannot rise from a chair without assistance. In children, rapid growth with accelerated bone maturation occurs. In patients over age 60, cardiovascular and myopathic manifestations predominate; the most common presenting complaints are palpitations, dyspnea on exertion, tremor, nervousness, and weight loss (see Chapter 23).

The eye signs of Graves disease have been classified by Werner as set forth in Table 7–9. This classification is useful in

TABLE 7–9 Classification of eye changes in Graves' disease.

Class	Definition
0	No signs or symptoms
1	Only signs, no symptoms (signs limited to upper lid retraction, stare, lid lag)
2	Soft tissue involvement (symptoms and signs)
3	Proptosis (measured with Hertel exophthalmometer)[a]
4	Extraocular muscle involvement
5	Corneal involvement
6	Sight loss (optic nerve involvement)

[a]Upper limits of normal according to race: Asian,18 mm; white, 20 mm; black, 22 mm. Increase in proptosis of 3-4 mm is mild involvement; 5-7 mm, moderate involvement; and over 8 mm, severe involvement. Other classes can be similarly graded as mild, moderate, or severe.

describing the extent of the eye involvement. However, it is not helpful in following the progress of the illness, because one class does not necessarily progress into the next. The first letters of each class form the mnemonic *NO SPECS*. Class 1 involves retraction of the upper lids associated with active thyrotoxicosis and usually resolves spontaneously when the thyrotoxicosis is adequately controlled. Lid retraction can be seen in any form of thyrotoxicosis, because it is due to adrenergic stimulation of the upper eyelid. Classes 2 to 6 represent true infiltrative disease involving orbital muscles and orbital tissues and are specific to Graves disease. Class 2 is characterized by soft tissue involvement with periorbital edema, congestion or redness of the conjunctiva, and edema of the conjunctiva (chemosis). Class 3 consists of proptosis as measured by the Hertel exophthalmometer. This instrument consists of two prisms with a scale mounted on a bar. The prisms are placed on the lateral orbital ridges, and the distance from the orbital ridge to the anterior cornea is measured on the scale (Figure 7–35). The upper limits of normal according to race are listed in the footnote to Table 7–9. Class 4 consists of extraocular muscle involvement, which typically is due to fibrosis and failure of muscle relaxation, limiting the function of the antagonist muscle. The inferior rectus is the muscle most commonly involved in the infiltrative process. By failing to relax normally, upward gaze limitation is the most common physical finding in patients with eye muscle involvement. The muscle next most commonly involved is the medial rectus, impairing lateral gaze. Class 5 is characterized by corneal involvement (keratitis) due to inability to close the eyes completely. Class 6 is a loss of vision from optic nerve involvement, likely due to ischemia of the nerve from compression of the surrounding enlarged extraocular muscles. As noted earlier, thyroid ophthalmopathy is due to infiltration of orbital fibroblasts and the extraocular muscles with lymphocytes and edema fluid due to an inflammatory reaction. The orbit is a cone enclosed by bone, and swelling of the extraocular muscles within this closed space causes proptosis of the globe and impaired muscle movement, resulting in diplopia. Ocular muscle enlargement can be demonstrated by orbital ultrasound, orbital CT scanning, or MRI (Figure 7–36). Although only about one-third of patients have eye involvement clinically, enlarged muscles can be detected by imaging in over 90% of patients.

Thyroid dermopathy consists of thickening of the skin, particularly over the lower tibia, due to accumulation of glycosaminoglycans (see Figure 7–33). It is relatively rare, occurring in about 2% to 3% of patients with Graves disease. It is usually associated with significant ophthalmopathy and with a very high serum titer of TSAb. The skin is markedly thickened with
a *peau d'orange* surface, and cannot be picked up between the fingers. Sometimes the dermopathy involves the entire lower leg and may extend onto the feet. Finally, bony involvement (osteopathy or thyroid acropathy), with subperiosteal bone formation and swelling, is particularly evident in the metacarpal bones (see Figure 7–34) and as clubbing of the digits. This too is a relatively rare finding. A more common finding in Graves disease is separation of the fingernails from their beds (onycholysis or Plummer nails), likely caused by rapid growth of the nails (Figure 7–37).

B. Laboratory findings   The laboratory findings in hyperthyroidism are summarized in Figure 7–38. The combination of an elevated FT_4 and a suppressed TSH makes the diagnosis of hyperthyroidism. Approximately 5% of patients have normal FT_4 levels but elevated serum T_3 levels, a situation termed **T_3 thyrotoxicosis**. Also, very mild Graves disease may result in FT_4

FIGURE 7–37 Onycholysis (separation of the nail from its bed) in Graves disease usually resolves spontaneously as the patient improves.

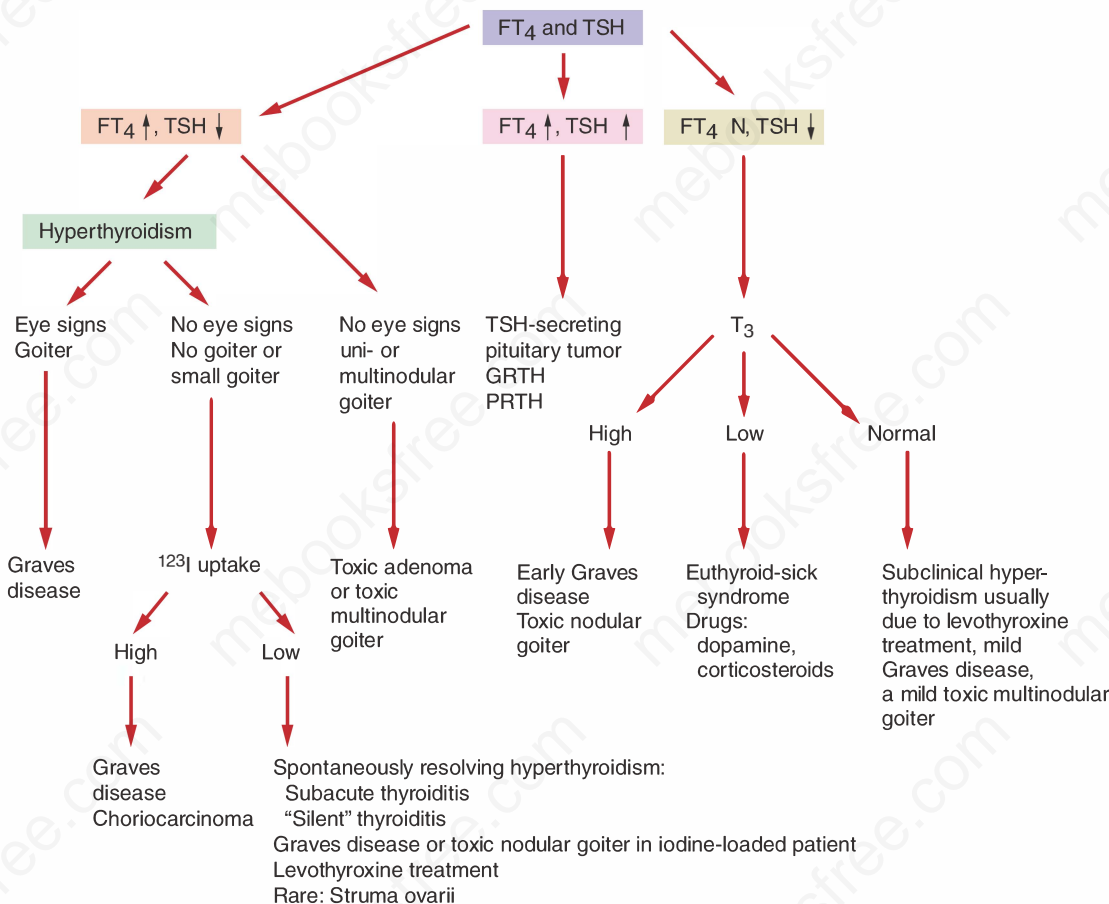

FIGURE 7–38 Laboratory tests useful in the differential diagnosis of hyperthyroidism (see text for details).

and T_3 serum levels that are within the range of normal but are high enough to lead to suppressed serum TSH levels, a situation termed **subclinical hyperthyroidism**. If both FT_4 and TSH are elevated and the RAIU is also elevated, consider a TSH-secreting pituitary tumor or generalized or pituitary-resistance syndromes. Patients who are severely ill may have low serum TSH levels but also have low serum FT_4 and T_3 levels (the so-called *sick euthyroid syndrome*).

In the condition called **familial dysalbuminemic hyperthyroxinemia**, an abnormal albumin is present in serum that preferentially binds T_4 but not T_3. This results in elevation of serum T_4 and FT_4I, and often the free T_4 when measured by usual clinical analogue free T_4 assays, but free T_4 is usually normal by equilibrium dialysis methods, as are serum T_3 and TSH. It is important to differentiate this euthyroid state from true hyperthyroidism. In addition to the absence of clinical features of hyperthyroidism, a normal serum T_3 and a normal TSH level rule out hyperthyroidism.

If eye signs are present, the diagnosis of Graves disease can be made without further tests. If eye signs are absent and the patient is hyperthyroid with or without a goiter, additional testing is needed. An elevated RAIU is typical of Graves disease. In contrast, a low uptake is seen in patients with several forms of spontaneously resolving hyperthyroidism, as in subacute thyroiditis or

silent thyroiditis, also termed **postpartum thyroiditis** (discussed later). A low RAIU is also found in patients who are iodine-loaded or who are taking T_4 therapy—or, rarely, in association with a struma ovarii, where ectopic thyroid tissue is located within an ovarian teratoma. Thyroid autoantibodies—to TG and TPO—are usually present in the serum in both Graves disease and *silent thyroiditis*, a variant of Hashimoto thyroiditis, but TSAb is relatively specific for Graves disease and typically is absent in other forms of thyrotoxicosis. This may be a useful diagnostic test in the patient who presents with unilateral or bilateral exophthalmos without obvious signs or laboratory manifestations of Graves disease (so-called "euthyroid Graves disease"). The ^{123}I or technetium scan is useful to evaluate the size of the gland as well as the presence of hot or cold nodules. CT and MRI scans of the orbits reveal extraocular muscle enlargement in most patients with Graves disease even when there is no clinical evidence of ophthalmopathy. In patients with clinical ophthalmopathy, orbital muscle enlargement may be striking (see Figure 7–36).

Other Presentations

Graves disease occasionally presents in an unusual or atypical fashion, in which case the diagnosis may not be obvious. Marked muscle atrophy may suggest severe myopathy that must be

differentiated from a primary neuromuscular disorder. *Thyrotoxic periodic paralysis* usually occurs in Asian males and presents with a sudden attack of flaccid paralysis and hypokalemia due to a shift of K^+ intracellularly. The paralysis usually subsides spontaneously and can be prevented by K^+ supplementation and β-adrenergic blockade. The illness is cured by appropriate treatment of the thyrotoxicosis (see Chapter 24). Patients with thyrocardiac disease, especially those over age 60, present primarily with symptoms of heart involvement—especially refractory atrial fibrillation insensitive to digoxin—or with high-output heart failure. About 50% of these patients have no evidence of underlying heart disease, and cardiac problems are cured by treatment of the thyrotoxicosis. Some older patients present with weight loss, small goiter, slow atrial fibrillation, and severe depression, with none of the clinical features of increased catecholamine reactivity. These placid patients have *apathetic thyrotoxicosis*. Finally, some young women may present with amenorrhea or infertility as the primary symptom. In all of these instances, the diagnosis of hyperthyroidism can usually be made on the basis of the clinical and laboratory studies described earlier.

Complications

Thyrotoxic crisis (thyroid storm) is the acute exacerbation of all of the symptoms and signs of thyrotoxicosis, often presenting as a syndrome that may be of life-threatening severity (see Chapter 24). Occasionally, thyroid storm may be mild and present simply as an unexplained febrile reaction after thyroid surgery in a patient who has been inadequately prepared. More commonly, it occurs in a more severe form after surgery, radioactive iodine therapy, or parturition in a patient with inadequately controlled thyrotoxicosis—or during a severe, stressful illness or disorder such as uncontrolled diabetes, trauma, acute infection, severe drug reaction, or myocardial infarction. The clinical manifestations of thyroid storm are marked hypermetabolism and excessive adrenergic response. Fever ranges from 38°C to 41°C and is associated with flushing and sweating. There is marked tachycardia, often with atrial fibrillation and high pulse pressure; occasionally heart failure occurs. Central nervous system symptoms include marked agitation, restlessness, delirium, and coma. Gastrointestinal symptoms include nausea, vomiting, diarrhea, and jaundice. A fatal outcome is associated with heart failure and shock.

At one time it was thought that thyroid storm was due to sudden release or dumping of stored T_4 and T_3 from the thyrotoxic gland. Careful studies have revealed, however, that the serum levels of T_4 and T_3 in patients with thyroid storm are not necessarily higher than in thyrotoxic patients without this condition. There is no evidence that thyroid storm is due to excessive production of T_3. In thyrotoxicosis, the number of adrenergic-binding sites for catecholamines increases, so that heart and other tissues have increased sensitivity to circulating catecholamines. In addition, there is decreased binding to TBG, with further elevation of free T_3 and T_4. One theory is that in this setting, with increased binding sites available for catecholamines, an acute illness, infection, or surgical stress triggers an outpouring of catecholamines which, in association with high levels of free T_4 and T_3, precipitates the acute problem.

The most striking clinical diagnostic feature of thyrotoxic crisis is hyperpyrexia out of proportion to other findings. Laboratory findings include elevated serum T_4, FT_4, and T_3 as well as a suppressed TSH (see Chapter 24).

Treatment of Graves Disease

Although autoimmune mechanisms are responsible for the syndrome of Graves disease, management has been largely directed toward controlling the hyperthyroidism. Three good methods are available: (1) antithyroid drug therapy, (2) surgery, and (3) radioactive iodine therapy.

A. Antithyroid drug therapy (see Figure 7–9)   The antithyroid drugs methimazole, carbimazole, and PTU act by inhibiting TPO-mediated iodination of TG to form T_4 and T_3 within the thyroid gland. PTU but not methimazole blocks peripheral T_4 to T_3 conversion; however, this effect is not generally considered to be clinically important except possibly in patients with severe thyrotoxicosis or thyroid storm. Carbimazole, used in the United Kingdom and parts of the British Commonwealth (eg, Australia, South Africa, and Singapore), is a precursor of methimazole that is rapidly metabolized to methimazole. Additionally, each of these drugs may have immunosuppressive effects that may be responsible for the remission from the disease that some patients have after 1 to 2 years of treatment. In general, antithyroid drug therapy as a first-line therapy is most useful in young patients with small glands and mild disease. The drug is given for 1 to 2 years, and then it is tapered or discontinued to see whether the patient has achieved a remission. Remissions, defined as normal thyroid function for 1 year following discontinuation of the antithyroid drug, occur in 20% to 50% of patients but may not be lifelong. Antithyroid drug therapy is generally started with larger doses. When the patient becomes biochemically euthyroid after 4 to 12 weeks, maintenance therapy may be achieved with a lower dose. Because of the potential for severe and potentially fatal hepatotoxicity with PTU, methimazole is the antithyroid drug of choice. Methimazole has fewer adverse reactions, has a longer duration of action, and single daily dosing leads to improved compliance. A typical regimen starts with a 10 to 20-mg dose of methimazole each morning for 1 to 2 months; this dose would then be reduced to 5 to 10 mg each morning for maintenance therapy. PTU could be considered in patients with mild allergic reactions to methimazole who prefer to remain on antithyroid drugs and is preferred in pregnant women in the first trimester because of rare teratogenic effects of methimazole in the fetus. A common regimen consists of giving PTU, 100 mg every 8 hours initially, and then in 4 to 8 weeks, reducing the dose to 50 to 200 mg once or twice daily. The laboratory tests of most value in early monitoring the course of therapy are serum FT_4 and T_3. TSH levels often remain suppressed for many weeks or even months, and hence

are not a reliable index of thyroid function early in the course of treatment.

An alternative method of therapy utilizes the concept of a total block of thyroid activity. The patient is treated with methimazole until euthyroid (about 3-6 months), but instead of continuing to taper the dose of antithyroid drug, at this point T_4 is added in a dose of about 0.1 mg/d. The patient then continues to receive the combination of antithyroid drug and T_4 (0.1 mg/d) for another 12 to 24 months. At the end of this time or when the size of the gland has returned to normal, the drugs are discontinued. This so-called "block-replace" regimen prevents the development of hypothyroidism due to excessive doses of antithyroid drugs, but the frequency of relapse is about the same as after treatment with antithyroid drugs alone. It is more expensive, because two drugs are needed, and there may be a greater frequency of side effects. Consequently, this strategy is not recommended for most patients.

1. **Duration of therapy and other factors related to remissions**—The duration of therapy with antithyroid drugs in Graves disease is usually 12 to 24 months; some patients prefer to be treated, if necessary, for prolonged periods of time (eg, decades) but this is not typical. A sustained remission is most likely in the following circumstances: (1) if the thyroid gland returns to normal size, (2) if the disease can be controlled with a relatively small dose of antithyroid drugs, and (3) if TSAbs are no longer detectable in the serum at the end of the course of therapy.

2. **Reactions to antithyroid drugs**—The adverse reactions to antithyroid drugs almost always occur within the first 3 months of therapy. They can be minor, especially a pruritic rash (about 5% of patients) or major, especially agranulocytosis (about 0.5% of patients). The rash can often be managed by administering antihistamines, and unless it is severe, it is not an indication for discontinuing the medication. Agranulocytosis requires immediate cessation of antithyroid drug therapy, institution of appropriate antibiotic therapy, and shifting to an alternative therapy, usually radioactive iodine. Agranulocytosis is usually heralded by a severe sore throat and fever. Thus, all patients receiving antithyroid drugs are instructed that if sore throat or fever develops, they should stop the drug, contact their physician, and obtain a white blood cell and differential count. If the white blood cell count is normal, the antithyroid drug can be resumed. Cholestatic jaundice with methimazole, hepatocellular toxicity and vasculitis with PTU, and acute arthritis with either drug are serious but rare side effects that also require cessation of drug therapy. As noted earlier, the severity of hepatotoxicity from PTU has led to the warning by the FDA that PTU be used only in special circumstances: in patients who are allergic to methimazole who are not candidates for radioiodine or surgery and in the first trimester of pregnancy. PTU may also be preferred in patients with thyroid storm, where the inhibition of T_4 to T_3 conversion may be clinically important.

B. Radioactive iodine therapy   In the United States, sodium iodide ^{131}I is the preferred treatment for most patients over age 21. In many patients without underlying heart disease, radioactive iodine may be given immediately in a dosage of 80 to 200 μCi/g of thyroid weight estimated on the basis of physical examination. The dosage is corrected for iodine uptake according to the following formula:

$$\text{Dose} = \frac{(80\text{-}200 \text{ microcuries/estimated gram of thyroid tissue}) \times \text{Estimated weight of thyroid (grams)}}{\text{Fractional 24-hour radioiodine uptake}}$$

Following the administration of radioactive iodine, which typically is given orally as a single capsule, the gland will shrink, and the patient will usually become euthyroid over a period of 2 to 6 months.

In elderly patients and in those with underlying heart disease or other medical problems, severe thyrotoxicosis, or large glands (>100 g), it is desirable to achieve a euthyroid state prior to ^{131}I therapy, because there may be occasional exacerbations of thyroid function in the weeks following radioiodine therapy. For this purpose, patients usually are treated with methimazole until they are euthyroid, medication is then stopped for 3 to 7 days, and the radioiodine therapy is given. Methimazole (or PTU) pretreatment have been associated with a diminished effectiveness of radioiodine therapy, which can be overcome by modestly increasing the dose of radioactive iodine.

Hypothyroidism is the almost inevitable complication of radioactive iodine therapy, ultimately developing in more than 80% of patients who are adequately treated. Hypothyroidism usually occurs in the first 6 to 12 months after therapy and is the best assurance that the patient will not have a recurrence of hyperthyroidism. Serum FT_4 and TSH levels should be followed every 6 to 8 weeks, and when hypothyroidism develops, prompt replacement therapy with T_4, 0.05 to 0.2 mg daily, is instituted. Long-term follow-up studies have shown that radioiodine therapy does not cause infertility, birth defects, or cancer later in life. Severe Graves eye disease is a contraindication to radioiodine therapy; several prospective studies have shown that radioiodine can exacerbate eye problems when they are present at baseline, and may even induce mild eye disease in those without eye disease. Patients with severe underlying hyperthyroidism, very high TSAb titers, and who smoke cigarettes are particularly prone to an exacerbation following radioiodine treatment. However, potential worsening can be prevented by the administration of prednisone 0.4 mg/kg/d for 1 to 2 months following the radioiodine treatment. Prednisone is typically used in patients with mild to moderate Graves eye disease, especially in those who smoke cigarettes.

Hypothyroidism may also occur as a late development after an earlier course of antithyroid drug therapy for Graves disease; in such patients, *burned-out* Graves disease is likely the end result of autoimmune thyroid destruction. Accordingly, all patients with Graves disease who have not become hypothyroid require lifetime follow-up to be certain that they remain euthyroid.

C. Surgical treatment   Total or near-total thyroidectomy is the treatment of choice for patients with very large glands or multinodular goiters, for patients with a concomitant suspicious or malignant thyroid nodule, for patients who are allergic to or

noncompliant with antithyroid drugs, for patients who refuse radioactive iodine, and for pregnant women with severe Graves disease who are allergic or develop reactions to antithyroid drugs. The patient is prepared with antithyroid drugs until euthyroid (about 6 weeks). In addition, starting 2 weeks before the day of operation, the patient may be given saturated solution of potassium iodide, 5 drops twice daily. This regimen is thought to diminish the vascularity of the gland and thereby decrease intraoperative blood loss.

An experienced surgeon is required, and total thyroidectomy is recommended, because if too much thyroid tissue is left behind, the disease may recur. Hypoparathyroidism and recurrent laryngeal nerve injury occur as complications of surgery in about 1% of cases, with lower rates in the hands of *high volume* surgeons.

D. Other medical measures During the acute phase of thyrotoxicosis, β-adrenergic–blocking agents are extremely helpful. Propranolol, 10 to 40 mg every 6 hours, or longer acting beta-blockers such as Inderal LA, nadolol, atenolol, or metoprolol control many adrenergic symptoms, tachycardia, hypertension, and atrial fibrillation. The drug is gradually withdrawn as serum FT_4 and T_3 levels return to normal. Adequate nutrition and rest are both essential. The oral cholecystographic dyes, sodium ipodate and iopanoic acid (no longer available in the United States), have been shown to inhibit both thyroid hormone synthesis and release as well as peripheral conversion of T_4 to T_3. In a dosage of 1 g daily, these drugs may help to rapidly restore the euthyroid state in very ill patients. They leave the gland saturated with iodide, so they should not be used immediately before ^{131}I therapy. Cholestyramine, 4 g orally 3 times daily, lowers serum T_4 by binding it in the gut, and may be useful in severely hyperthyroid patients.

Choice of Therapy

The choice of therapy varies with the nature and severity of the illness and prevailing customs. For example, in the United States, radioiodine therapy has been the preferred treatment for the average patient, whereas in Europe, Latin America, and Asia, primary antithyroid drug therapy is preferred. In general, antithyroid drugs are a reasonable initial therapy for children and adolescents and in adults with mild disease and small goiters. In all other patients, radioiodine should be strongly considered. In contemporary U.S. clinical practice, the role of surgery is limited to noncompliant patients who refuse radioiodine, patients with large goiters, and women desirous of pregnancy in the near future who do not want to take antithyroid drugs in pregnancy.

Treatment of Complications

A. Thyrotoxic crisis Thyrotoxic crisis (thyroid storm) requires vigorous management. Propranolol, 1 to 2 mg slowly intravenously every 5 to 10 minutes for a total of 10 mg, or 40 to 80 mg every 6 hours orally, is helpful in controlling arrhythmias. Large doses of propranolol also have the ability to block T_4 to T_3 conversion. Esmolol, a very rapidly acting beta-blocker, is given at a dose of 250 to 500 mg/kg/min as a loading dose followed by 50 μg/kg/min with cardiac monitoring. In the presence of severe heart failure or asthma and arrhythmia, where beta-blockers may be contraindicated, cautious intravenous administration of verapamil in a dose of 5 to 10 mg may be effective. Hormone synthesis is blocked by the administration of PTU, 250 mg every 6 hours. In thyroid storm, PTU may be preferable to methimazole because PTU blocks T_4 to T_3 conversion. If the patient is unable to take medication by mouth, methimazole in a dose of 60 mg every 24 hours or PTU, 400 mg every 6 hours, can be given by rectal suppository or enema.[4] After administration of an antithyroid drug, hormone release is retarded by the oral administration of a saturated solution of potassium iodide, 10 drops twice daily. As noted earlier, the oral cholecystographic agents, sodium ipodate (Oragrafin) or iopanoic acid (Telepaque), provide a source of iodine and potently block T_4 to T_3 conversion, but these drugs are not available currently in the United States. The administration of hydrocortisone hemisuccinate, or its equivalent, 50 mg intravenously every 6 hours, is usually recommended, but its role in thyroid storm management is uncertain. Supportive therapy includes a cooling blanket and acetaminophen to help control fever. Aspirin is contraindicated because of its tendency to bind to TBG and displace T_4, rendering more T_4 available in the free state. Proper fluid, electrolyte, and nutritional support are important. For sedation, phenobarbital may be useful because it accelerates the peripheral metabolism and inactivation of T_4 and T_3. Oxygen, diuretics, and digoxin are indicated for heart failure and/or atrial fibrillation. Finally, it is essential to treat the underlying disease process that may have precipitated the acute exacerbation. As an extreme measure (rarely needed) to control thyrotoxic crisis, plasmapheresis or peritoneal dialysis may be used to remove high levels of circulating-free thyroid hormones (see Chapter 24).

B. Ophthalmopathy For mild disease, keeping the patient's head elevated at night and the administration of diuretics may help diminish periorbital edema. As noted earlier, prednisone begun immediately after radioiodine in a dose of 0.4 mg/kg/d, reducing the dose by 10 mg every 2 weeks, protects against exacerbation of ophthalmopathy following ^{131}I therapy. Management of severe ophthalmopathy due to Graves disease involves close cooperation between the endocrinologist and the ophthalmologist. For severe acute inflammatory reactions, a

[4] **Preparation of rectal methimazole:** Dissolve 1200 mg methimazole in 12 mL of water to which a mixture of two drops of Span 80 in 52 mL of cocoa butter warmed to 37°C has been added. Stir the mixture to form a water-oil emulsion, pour into 2.6 mL suppository molds, and cool. Each suppository supplies approximately 60 mg methimazole-absorbed dose (Nabil et al., 1982).
Preparation of rectal PTU: Dissolve 400 mg PTU in 60 mL of Fleet Mineral Oil for the first dose and then dissolve 400 mg PTU in 60 mL of Fleet Phospho-Soda for subsequent enemas.

short course of high-dose corticosteroid therapy is frequently effective. Weekly pulse therapy with high doses of intravenous methylprednisolone (500 mg weekly for 6 weeks followed by 250 mg weekly for 6 weeks) has been shown to be more effective and less toxic than oral prednisone therapy. If corticosteroid therapy is not effective or if there is recurrence after the drug is tapered, external x-ray therapy to the retrobulbar area may be helpful. The dose is usually 2000 cGy in 10 fractions given over a period of 2 weeks. The lens and anterior chamber structures must be shielded.

In very severe cases or where vision is threatened, orbital decompression can be used. One operation involves a transantral approach through the maxillary sinus, removing the floor and the lateral walls of the orbit. In the alternative anterior approach, the orbit is entered under the globe, and portions of the floor and the walls of the orbit are removed. Both approaches are effective, and exophthalmos can be reduced by 5 to 7 mm in each eye by these techniques. After the acute process has subsided, the patient is frequently left with double vision or lid abnormalities owing to muscle fibrosis and contracture or the postoperative position of the globe. These problems can be corrected by cosmetic lid surgery or eye muscle surgery.

C. Thyrotoxicosis and pregnancy   Thyrotoxicosis during pregnancy presents a special problem. It is unusual, affecting approximately 0.1% of pregnancies. It is important to recall that serum TSH levels may be subnormal at the end of the first trimester in up to 20% of normal women. This is due to the effects of serum hCG, the levels of which normally peak at the end of the first trimester; hCG activates the TSH receptor. This is a transient phenomenon and is physiologic, not pathologic. Hyperemesis gravidarum may cause mild hyperthyroidism (so-called *gestational thyrotoxicosis*), which is likely due to extremely high-serum levels of hCG, present in this condition, that stimulates the TSH receptor. However, no treatment is indicated, because the hyperthyroid state resolves when the hyperemesis resolves, usually by midgestation.

In pregnant patients with Graves disease, the patient is treated with antithyroid drugs throughout most of the pregnancy, postponing the decision regarding long-term management until after delivery. Radioactive iodine is absolutely contraindicated because it crosses the placenta freely and may injure the fetal thyroid. The dosage of antithyroid drugs must be kept to the minimum necessary to control symptoms, because both PTU and methimazole cross the placenta and may affect the function of the fetal thyroid gland. PTU is preferred over methimazole because methimazole has rare severe teratogenic effects (aplasia cutis and methimazole embryopathy [choanal atresia, tracheoesophageal fistulae, and other defects]). While PTU use has also been associated with birth defects, these are not as severe (eg, renal cysts and preauricular sinuses). Current recommendations advise limiting PTU use to the first trimester, and then switching to methimazole. However, methimazole can be used when PTU allergy or a poor clinical response to PTU is present. If the disease can be controlled by initial doses of PTU of 250 mg/d (in divided doses) or less and

maintenance doses of 25 to 100 mg/d, the likelihood of fetal hypothyroidism is extremely small. The FT_4I or FT_4 should be maintained in the upper range of normal for nonpregnant women by appropriately reducing the antithyroid drug dosage. In a significant minority of patients, the drug can be discontinued in the latter part of pregnancy because of spontaneous disappearance of TSAb. Serum levels of TSAb should be measured in the third trimester; high titers can be associated with neonatal Graves disease (see later). Breastfeeding is permissible with either antithyroid drug, because the low levels found in breast milk do not affect thyroid function in the neonate.

Graves disease may occur in the newborn infant (*neonatal Graves disease*) due to transplacental passage of TSAb. Although most infants with this rare syndrome are born to mothers with active Graves disease, it occasionally can occur in infants born to hypothyroid mothers who have been treated for Graves disease with radioiodine in the past but who still retain circulating TSAb. The disease may not be evident at birth, because the antithyroid drugs used to treat the mother can cross the placenta and affect the infant's thyroid as well. The child is born small, with weak muscles, tachycardia, fever, and frequently with distress or neonatal jaundice. Examination reveals an enlarged thyroid gland and occasionally prominent, puffy eyes. The heart rate is rapid, temperature is elevated, and heart failure may ensue. Laboratory studies reveal an elevated FT_4I or FT_4, a markedly elevated T_3, and usually a low TSH—in contrast to normal infants, who have elevated TSH at birth. Bone age may be accelerated. TSAb is usually found in the serum of both the infant and the mother. The pathogenesis of this syndrome is thought to involve transplacental transfer of TSAb from mother to fetus, with subsequent development of thyrotoxicosis. The disease is self-limited and subsides over a period of 4 to 12 weeks, coinciding with the fall in the child's serum TSAb levels. Therapy for the infant includes PTU in a dose of 5 to 10 mg/kg/d (in divided doses at 8-hour intervals); Lugol solution, one drop (8 mg potassium iodide) every 8 hours; and propranolol, 2 mg/kg/d in divided doses. In addition, adequate nutrition, antibiotics for infection if present, sedatives if necessary, and supportive therapy are indicated. If the child is very thyrotoxic, corticosteroid therapy (prednisone, 2 mg/kg/d) partially blocks conversion of T_4 to T_3 and may be helpful in the acute phase. The above medications are gradually reduced as the child improves and can usually be discontinued by 6 to 12 weeks.

Maternal sera may also contain TSAb that functions as blocking Abs that can cross the placenta to produce transient hypothyroidism in the infant. This condition may need to be treated with T_4 supplementation for a short time.

Course and Prognosis

In general, the course of Graves disease treated with antithyroid drugs is one of remissions and exacerbations over a protracted period of time, unless the gland is destroyed by surgery or radioactive iodine. Although some patients may remain euthyroid for long periods after antithyroid drug treatment, at least 25% eventually develop hypothyroidism. Lifetime follow-up is therefore indicated for all patients with Graves disease.

2. OTHER FORMS OF THYROTOXICOSIS

Toxic Adenoma

A functioning adenoma hypersecreting T_3 and T_4 causes hyperthyroidism. These lesions start out as a small autonomously functioning nodule that slowly increases in size to produce excessive quantities of thyroid hormones. This gradually suppresses endogenous TSH secretion, which results in reduced function of the contralateral lobe of the gland (Figure 7–39). The typical patient is an older individual (usually >40) who has noted recent growth of a long-standing thyroid nodule. Symptoms of weight loss, weakness, shortness of breath, palpitations, tachycardia, and heat intolerance are noted. Infiltrative ophthalmopathy is never present.

Physical examination reveals a definite nodule on one side, with very little thyroid tissue on the other side. Laboratory studies usually reveal suppressed TSH and elevation in serum T_3 levels, often with only borderline elevation of FT_4 levels. A radionuclide scan reveals that the nodule is hot, with diminished or absent function of the contralateral lobe. Toxic adenomas are usually benign follicular adenomas and almost never malignant.

Treatment with radioactive iodine is generally effective and is attractive because the contralateral lobe can be spared the destructive effects of the radiation, and the patient should therefore remain euthyroid. Radioiodine therapy in doses of 20 to 30 mCi is usually required to destroy the benign neoplasm. If antithyroid drugs are used to pretreat the patient, it is important that the serum TSH remain low, so that the contralateral lobe will not be stimulated to take up the radioiodine. Surgery is an option, if the nodule is very large and causing obstructive symptoms such as dysphagia, neck pressure, or difficulty breathing. Antithyroid drugs may be used to normalize thyroid function prior to radioiodine or surgery but are not a good long-term solution, because, unlike the situation with Graves disease, remissions do not occur.
Toxic Multinodular Goiter (Plummer Disease)

This disorder usually occurs in older patients with longstanding euthyroid multinodular goiter. The patient presents with tachycardia, heart failure, or arrhythmia and sometimes weight loss, nervousness, weakness, tremors, and sweats. Physical examination reveals a multinodular goiter that may be small or quite large and may even extend substernally. Laboratory studies reveal a suppressed TSH and elevation in serum T_3 levels, with less striking elevation of serum T_4. Radioiodine scan reveals multiple functioning nodules in the gland or occasionally an irregular, patchy distribution of radioactive iodine (Figure 7–40).

Hyperthyroidism in patients with longstanding multinodular goiters can be precipitated by the administration of pharmacologic doses of iodide-containing drugs (called the Jod-Basedow phenomenon or iodide-induced hyperthyroidism). The pathophysiology of iodine-induced hyperthyroidism is unknown but likely involves the inability of some thyroid nodules to adapt to an iodide load, with resulting excess hormone production. This is one mechanism for the development of hyperthyroidism after administration of the iodine-containing antiarrhythmic drug amiodarone (see later).

The management of toxic nodular goiter may be difficult, because patients are often elderly with other comorbidities. Control of the hyperthyroid state with antithyroid drugs followed by radioiodine is the therapy of choice. If the goiter is very large, thyroidectomy can be contemplated if the patient is a good surgical candidate.

Amiodarone-Induced Thyrotoxicosis

Amiodarone is an antiarrhythmic drug that contains 37.3% iodine by weight. In the body, it is stored in fat, myocardium,

FIGURE 7–39 Solitary toxic nodule as it appears on ^{99m}Tc pertechnetate scan. Note suppression of contralateral lobe (left) by toxic nodule (right).

liver, and lung and has a half-life of about 50 days. In the United States, about 2% of patients treated with amiodarone develop amiodarone-induced thyrotoxicosis. In some patients, the thyrotoxicosis is due to the excess iodine (also called type 1 amiodarone-induced thyrotoxicosis); in others, it is due to an amiodarone-induced thyroiditis, with inflammation and release of stored hormone into the bloodstream as the result of thyroidal inflammation (also termed type 2 amiodarone-induced thyrotoxicosis). In general, the thyrotoxicosis associated with excess iodine occurs within 6 to 12 months of starting amiodarone therapy, while patients developing thyroiditis have usually been taking the drug for 2 to 3 years. Thyroid ultrasound with Doppler examination of the thyroid circulation may be helpful in differentiating the two syndromes: the thyroidal blood flow is increased in iodide-induced hyperthyroidism and diminished in thyroiditis. Treatment is often difficult. Iodide-induced thyrotoxicosis can be controlled with methimazole, 40 to 60 mg/d, and β-adrenergic blockade. Although potassium perchlorate (250 mg every 6 hours) could be added to block further iodide uptake, long-term, high-dose treatment with this agent has been associated with aplastic anemia and requires careful monitoring. Also, this drug is no longer available in the United States. The drug-induced thyroiditis responds to prednisone therapy, which may need to be continued for several months. Some patients have what appears to be a mixed form of disease and respond to a combination of antithyroid drugs and prednisone. Total thyroidectomy is curative and may be needed in patients who are nonresponsive to pharmacologic therapy. Of course, surgery is feasible only if the patient can withstand the stress of surgery (see Chapter 24).

Subacute and Silent Thyroiditis

These entities will be discussed in a separate section, but it should be mentioned here that thyroiditis, either subacute or silent, may present with symptoms of mild to severe thyrotoxicosis following an acute release of T_4 and T_3 into the circulation. These illnesses can be differentiated from other forms of thyrotoxicosis in that the RAIU is markedly suppressed, and the symptoms usually subside spontaneously over a period of weeks or months.

Thyrotoxicosis Factitia

This is a psychoneurotic disturbance in which the patient surreptitiously ingests excessive amounts of T_4 or thyroid hormone preparations, usually for purposes of weight control. The individual, usually a woman, is often someone connected with the health-care field who can easily obtain thyroid medication. Features of thyrotoxicosis, including weight loss, nervousness, palpitation, tachycardia, and tremor, may be present, but goiter and eye signs are absent. Characteristically, TSH is suppressed, serum FT_4 and T_3 levels are elevated, serum TG is low, and RAIU is nil. Management requires careful discussion of the hazards of long-term thyroid hormone therapy, particularly cardiovascular damage, muscle wasting, and osteoporosis. Formal psychotherapy may be necessary.

Rare Forms of Thyrotoxicosis

A. Struma ovarii   In this syndrome, a teratoma of the ovary contains thyroid tissue that becomes hyperactive. Mild features of thyrotoxicosis result, such as weight loss and tachycardia, but there is no evidence of goiter or eye signs. Serum FT_4 and T_3 are mildly elevated, serum TSH is suppressed, and RAIU over the neck is low. Total body scan reveals uptake of radioiodine in the pelvis, rather than in the neck. The disease is curable by removal of the teratoma.

B. Thyroid carcinoma   Follicular carcinoma of the thyroid may concentrate radioactive iodine, but only rarely does it retain the ability to convert this iodide into active hormone. Only a few cases of metastatic thyroid cancer are described in which patients have presented with hyperthyroidism. The clinical picture consists of weakness, weight loss, palpitations, and a thyroid nodule but no ophthalmopathy. Body scan with ^{131}I reveals areas of uptake usually distant from the thyroid (eg, bone or lung). Treatment with large doses of radioactive iodine may destroy the metastatic deposits and treat the hyperthyroidism.

C. Hydatidiform mole and choriocarcinoma   Hydatidiform moles and choriocarcinomas produce high levels of hCG, which has intrinsic TSH-like activity. This may induce thyroid hyperplasia, increased RAIU, suppressed TSH, and mild elevation of serum T_4 and T_3 levels. It is rarely associated with overt thyrotoxicosis and is curable by removal of the mole or treatment of the tumor.

D. Hamburger thyrotoxicosis   In the 1970s an epidemic of thyrotoxicosis in the midwestern United States was traced to hamburger made from *neck trim*, the strap muscles from the necks of slaughtered cattle that contained beef thyroid tissue. The United States Department of Agriculture has now prohibited the use of this material for human consumption.

E. Syndrome of inappropriate TSH secretion   A group of patients have been reported with elevated serum FT_4 concentrations in association with elevated or inappropriately normal serum immunoreactive TSH levels. This has been called the **syndrome of inappropriate TSH secretion**. Two conditions may explain this unusual combination of laboratory values: (1) TSH-secreting pituitary adenoma, and (2) non-neoplastic pituitary hypersecretion of TSH.

Patients with TSH-secreting pituitary adenomas usually present with mild thyrotoxicosis and goiter and may have a concurrent pituitary hormonal deficiency, such as central hypogonadism causing amenorrhea or impotence. Rarely, a TSH-secreting tumor may cosecrete other pituitary hormones such as growth hormone or prolactin. There are no eye signs of Graves disease. Laboratory evaluation reveals elevated FT_4 and T_3, whereas serum TSH, usually undetectable in Graves disease, is within the normal range or even elevated. The TSH α subunit secretion from these tumors is markedly elevated; a molar ratio of α subunit: TSH greater than

5.7 is usually diagnostic of the presence of a TSH-secreting pituitary adenoma.[5]

In addition, the increased serum TSH is not suppressible with high doses of exogenous thyroid hormones. Visual field examination may reveal a bitemporal defect, and CT or MRI of the sella usually reveals a pituitary tumor. Management usually involves control of the thyrotoxicosis with antithyroid drugs and removal of the pituitary tumor via transsphenoidal hypophysectomy. These tumors are often quite aggressive and may extend widely out of the sella. If the tumor cannot be completely removed, it may be necessary to treat residual tumor with radiation therapy and to control thyrotoxicosis with radioactive iodine. Long-acting somatostatin analog (octreotide) suppresses TSH secretion in many of these patients and may even inhibit tumor growth in some.

Non-neoplastic pituitary hypersecretion of TSH is essentially a form of tissue resistance to T_3 and T_4. This is discussed in the following section.

Resistance to Thyroid Hormone Syndromes

Thyroid hormone action is mediated by nuclear thyroid hormone receptors (TRs), TRα and TRβ, which are encoded by the *THRA* and *THRB* genes, respectively. Two forms of RTHs are recognized. The first is GRTH, which can be caused by a number of different mutations in *THRB*, which confers resistance to TRβ, leading to elevated serum levels of the thyroid hormones and a TSH level that is inappropriately normal or slightly elevated. The second is resistance to thyroid hormone receptor alpha (RTHα) caused by *THRA* mutations, which are associated with a low serum TSH and slightly low FT_4 level. In both conditions, most patients are heterozygous for a single mutant TR gene (either THRB or THRA) that produces a mutant protein capable of inhibiting thyroid hormone actions by a dominant negative mechanism (see later).

GRTH was first described in 1967 as a familial syndrome of deaf mutism, stippled epiphyses, goiter, and high circulating thyroid hormone levels with normal TSH. The clinical presentation as reported in more than 500 cases has been variable. Although most affected individuals are clinically euthyroid; some present with goiter, stunted growth, delayed maturation, attention deficits, hyperactivity disorders, and resting tachycardia. The disorder is familial in 75% of cases, and inheritance is autosomal dominant. Laboratory tests reveal elevated serum T_4, FT_4, and T_3 with normal or elevated TSH. Testing to distinguish GRTH from TSH-secreting adenomas usually reveals a fall in TSH with T_3 administration, a molar ratio of α subunit-to-TSH of less than 1 and a pituitary MRI without evidence of a pituitary tumor in GRTH. Molecular studies have revealed point mutations in the carboxyl terminal ligand-binding portion of TRβ, which produces a defective TR that demonstrates reduced binding to T_3 while retaining the ability to bind to DNA. The mutant TR exerts a dominant negative action by occupying the TRE as either an inactive homodimer or heterodimer, both of which repress gene expression (see Figures 7–20 and 7–21). While distinct point mutations in different families may account, in part, for differences in clinical expression of the syndrome, there can be considerable phenotypic variation in a single kindred. Identifying the specific mutation in affected individuals does allow use of molecular screening methods for the diagnosis of the syndrome in other family members.

In most patients with GRTH, the increased levels of T_3 and T_4 appear to compensate largely for the receptor defect, and treatment is unnecessary. In fact, some patients have been erroneously thought to have Graves disease and inappropriately undergone therapy with radioiodine or surgery. However, in some children, administration of thyroid hormones may be necessary to correct defects in growth or mental development.

Some individuals with GRTH have symptoms of mild hyperthyroidism suggesting that their degree of thyroid hormone resistance varies from tissue to tissue. This is consistent with the observation that identical *THRB* gene mutations have been found in patients with various degrees of clinical thyroid hormone resistance. If the hyperthyroid state in such individuals is causing significant symptoms, therapy with beta-adrenergic–blocking agents, antithyroid drugs, or even radioactive iodine can be considered.

The first patient with RTHα was reported in 2012. This individual, and subsequently several others, have delayed growth, failed tooth eruption, constipation, low intellectual function, and decreased heart rate. These clinical features are consistent with an abnormal TRα protein, which is expressed predominantly in the skeleton, heart, and likely the intestine. Affected individuals' thyroid function tests typically include a low-normal FT_4, high-normal or elevated T_3, and normal TSH.

TSH Receptor Gene Mutations

Mutations in the *TSH receptor* (*TSH-R*) gene can produce a variety of clinical syndromes. Somatic mutations in the seven-transmembrane loop of the *TSH-R* may activate the receptor, producing solitary or multiple hyperfunctioning adenomas, whereas germline mutations may result in congenital hyperthyroidism in the newborn that can mimic neonatal Graves disease. Mutations in the extracellular amino terminal portion of the *TSH-R* produce resistance to TSH with uncompensated or compensated hypothyroidism. Some patients may have normal serum FT_4 and T_3 levels and normal growth and development but persistently elevated serum TSH. Others may be severely hypothyroid (cretinoid), with low FT_4 levels, elevated TSH, and no response to exogenous TSH. In this group, the defect may be in the coupling of *TSH-R* and the G_s protein necessary for activation of adenylyl cyclase.

NONTOXIC GOITER

Etiology

Nontoxic goiter (ie, goiter not associated with hyperthyroidism) can be diffuse or nodular. In some circumstances, it results from

---

[5]The α subunit-TSH molar ratio is calculated as follows: (α subunit in μg/L divided by TSH in mU/L) × 10. Normal range (for a patient with normal TSH and gonadotrophins) is less than 1.

TSH stimulation, which in turn results from inadequate thyroid hormone synthesis. Some goiters are due to mutations in genes involved in thyroid growth and/or thyroid function. In many patients, however, the cause of the goiter is obscure, because serum TSH levels are normal. Worldwide, iodine deficiency remains the most common cause of nontoxic goiter or *endemic goiter*. With the widespread use of iodized salt and the introduction of iodides into fertilizers, animal feeds, and food preservatives, iodide deficiency in developed countries has become relatively rare, and it probably does not exist in the United States. However, there are large areas of Africa, the mountainous areas of central Asia, parts of central Europe, and Papua New Guinea, where iodine intake is still deficient. Even highly developed countries, including Australia and the United Kingdom, have recently been found to have mild to moderate iodine deficiency. Optimal iodine requirements for adults are in the range of 150 to 300 µg/d. In endemic goiter areas, the daily intake (and urinary excretion) of iodine falls below 50 µg/d; in areas where iodine is extremely scarce, excretion falls below 20 µg/d. It is in these areas that 90% of the population has goiters, and 5% to 15% of infants are born with myxedematous or neurologic changes of cretinism. The variability in the extent of goiter in these areas may be related to the presence of other, unidentified goitrogens such as goitrin, an organic compound found in certain roots and seeds; and cyanogenic glycosides, found in cassava and cabbage, that release thiocyanate that can exacerbate the effects of iodide deficiency. In addition, compounds such as phenols, phthalates, pyridines, and polyaromatic hydrocarbons found in industrial waste water are weakly goitrogenic.

The most common cause of thyroid enlargement in developed countries is chronic thyroiditis (Hashimoto thyroiditis; see later). The cause of goiter not due to autoimmune thyroid disease or iodine sufficiency is uncertain. In some patients, mild defects in thyroid hormone synthesis (dyshormonogenesis) (discussed earlier in the section Hypothyroidism) may result in goiter with relatively normal thyroid function. Finally, thyroid enlargement can be due to gene mutations producing a benign lesion, such as adenoma, or to a malignant one, such as carcinoma.

Pathogenesis

The development of nontoxic goiter in patients with dyshormonogenesis or severe iodine deficiency involves impaired hormone synthesis and, secondarily, an increase in TSH secretion. TSH induces diffuse thyroid hyperplasia, followed by focal hyperplasia with necrosis and hemorrhage, and finally the development of new areas of focal hyperplasia. Focal or nodular hyperplasia usually involves a clone of cells that may or may not be able to concentrate iodine or synthesize TG. Thus, the nodules vary from hot nodules that can concentrate iodine to cold ones that cannot, and from colloid nodules that can synthesize TG to microfollicular ones that cannot. Initially, the hyperplasia is TSH dependent, but later the nodules become TSH independent, or autonomous. Thus, a diffuse nontoxic TSH-dependent goiter may progress over an extended period of time to become a toxic multinodular TSH-independent goiter.

The mechanism for the development of autonomous growth and function of thyroid nodules may involve mutations that activate the G_s protein in the cell membrane. Mutations of this gene, called the *gsp* oncogene, have been found in a high proportion of nodules from patients with multinodular goiter. Chronic activation of the G_s protein results in thyroid cell proliferation and hyperfunction even when TSH is suppressed.

In iodine-sufficient parts of the world such as the United States, euthyroid nontoxic goiter is a very common problem affecting up to 15% of women. The cause of goiter in the absence of iodine deficiency, autoimmunity, or obvious biosynthetic defects is unknown. In some kindreds with euthyroid multinodular goiter, mutations in the *TG* gene have been identified, suggesting the presence of subclinical or mild defects in thyroid hormone synthesis that do not cause overt hypothyroidism or even elevation in serum TSH levels.

Clinical Features

A. Symptoms and signs   Patients with nontoxic goiter usually present with thyroid enlargement, which, as noted earlier, may be diffuse or multinodular. The gland may be relatively firm but is often soft or rubbery in consistency. Over a period of time, the gland may become progressively larger, so that in long-standing cases, huge goiters may develop and extend substernally to the level of the aortic arch. Facial flushing and dilation of cervical veins on lifting the arms over the head is a positive **Pemberton sign** and indicates obstruction to jugular venous flow (Figure 7–41). The patient may complain of pressure symptoms in the neck, particularly on moving the head upward or downward, and of difficulty in swallowing. Vocal cord paralysis due to recurrent laryngeal nerve involvement is rare. The vast majority of patients are euthyroid. Thyroid enlargement probably represents compensated hypothyroidism.

B. Laboratory findings   Laboratory studies reveal a normal FT_4 and, usually, normal levels of TSH. The increased mass of thyroid tissue may compensate for inefficient synthesis of hormone. RAIU may be high, normal, or low, depending on the iodide pool and the serum TSH level.

C. Imaging studies   Isotope scanning usually reveals a patchy uptake, frequently with focal areas of increased uptake corresponding to hot nodules and areas of decreased uptake corresponding to cold nodules. Thyroid ultrasound is a simple way to follow the growth of the goiter and in addition may reveal cystic changes and coarse calcifications in one or more of the nodules, representing previous hemorrhage and necrosis. Cross sectional imaging with CT scan allows the delineation of tracheal deviation or compression as well as possible substernal extension of the goiter.

Differential Diagnosis

The major problem in differential diagnosis is to rule out cancer. This will be discussed in the section Thyroid Carcinoma.

FIGURE 7–41   Pemberton sign (facial plethora) when the arms are raised above the head due to obstruction of jugular venous flow as the thyroid is forced downward into the sternal notch. This patient has a large goiter shown on an MRI. (Reproduced with permission from Basaria S, Salvatori R. Pemberton sign. *N Engl J Med*. 2004 Mar 25;350(13):1338.)

Treatment

With the exception of those due to neoplasm, the current management of nontoxic goiters consists simply of observation, without any specific therapy. Nontoxic goiters are very slow growing and usually do not cause compressive symptoms or thyroid dysfunction. Thyroid hormone suppression therapy rarely results in clinically significant decrements in goiter size. Also, longstanding goiters may have areas of necrosis, hemorrhage, and scarring as well as autonomously functioning nodules that will not regress on T_4 therapy. Furthermore, to suppress the serum TSH level, doses of T_4 are required that could cause harm, especially in elderly patients who are at risk of developing atrial fibrillation and osteoporosis. Also, many nontoxic goiters have areas of autonomy within them that do not depend on TSH for function, and therefore, will not decrease in size and may contribute to the iatrogenic hyperthyroidism.

Surgery is indicated for goiters that continue to grow or that produce obstructive symptoms. Substernal extension of a goiter is not, in and of itself, an indication for surgical removal. A large multinodular goiter with tracheal deviation and substernal extension is shown in Figure 7-42. Although multinodular goiters are rarely malignant, the size of the mass with resulting pressure symptoms may require subtotal thyroidectomy.

FIGURE 7–42 Massive multinodular goiter (arrow) with substernal extension causing tracheal narrowing and deviation to the right.

If the patient is not a suitable candidate for surgery, radioiodine ablation of functioning thyroid tissue may provide palliative relief of obstructive symptoms. An adequate dose of radioiodine reduces the size of the goiter about 30% to 50% and usually alleviates obstructive symptoms.

Course and Prognosis

Patients with nontoxic goiter should avoid pharmacologic doses of iodides, which may induce either hyperthyroidism or, in the presence of thyroidal autoimmunity, hypothyroidism. Occasionally, single adenomas or several adenomas become hyperfunctional, producing a toxic nodular goiter (discussed earlier). Nontoxic goiter is often familial and other members of the family should be examined and observed for the possible development of goiter.

THYROIDITIS

1. SUBACUTE THYROIDITIS

Subacute thyroiditis (De Quervain thyroiditis or granulomatous thyroiditis) is an acute inflammatory disorder of the thyroid gland most likely due to viral infection. A number of viruses, including mumps virus, coxsackievirus, and adenoviruses, have been implicated, either by finding the virus in biopsy specimens taken from the gland or by demonstration of rising titers of viral Abs in the blood during the course of the infection. Pathologic examination reveals moderate thyroid enlargement and a mild inflammatory reaction involving the capsule. Histologic features include destruction of thyroid parenchyma and the presence of many large phagocytic cells, including giant cells. Subacute thyroiditis is more common in the summer months, in women, and in individuals who are HLA-Bw35 positive.

Clinical Features

A. Symptoms and signs   Subacute thyroiditis usually presents with fever, malaise, and soreness in the anterior neck, which may extend up to the angle of the jaw or toward the ear lobes on one or both sides of the neck. Initially, the patient may have symptoms of hyperthyroidism, with palpitations, nervousness, and sweats. There is no ophthalmopathy. On physical examination, the gland is exquisitely tender, so that the patient objects to pressure on it. There are no signs of local redness or heat suggestive of abscess formation. Clinical signs of thyrotoxicosis, including tachycardia, tremor, and hyperreflexia, may be present.

B. Laboratory findings   Laboratory studies vary with the course of the disease (Figure 7–43). Initially, FT_4 and T_3 are elevated, whereas serum TSH and RAIU are extremely low. Because the thyroid hormone levels in the blood are a reflection of leakage of glandular hormonal stores, serum FT_4 levels are elevated disproportionately to serum T_3 levels. The erythrocyte sedimentation rate is markedly elevated, sometimes greater than 100 mm/h by the Westergren scale. Thyroid autoantibodies are usually not detectable in serum. As the disease progresses, FT_4 and T_3 drop, TSH rises, and symptoms of hypothyroidism may be noted. Later, RAIU rises, reflecting recovery of the gland from the acute insult.

Differential Diagnosis

Subacute thyroiditis can be differentiated from other viral illnesses by the involvement of the thyroid gland. It is differentiated from

FIGURE 7–43 Changes in serum T_4 and radioactive iodine uptake in patients with subacute, silent, and postpartum thyroiditis. In the initial phase, serum T_4 is elevated and the patient may have symptoms of thyrotoxicosis, but radioactive iodine uptake is markedly suppressed. The illness may pass through phases of euthyroidism and hypothyroidism before remission. (Data from Woolf PD, Daly R. Thyrotoxicosis with painless thyroiditis. *Am J Med*. 1976 Jan; 60(1):73-79.)

Graves disease by the presence of thyroidal pain, low RAIU associated with elevated serum T_3 and FT_4 and suppressed serum TSH, and by the absence of thyroid Abs.

Treatment

In many cases, only symptomatic treatment is necessary (eg, aspirin or other nonsteroidal anti-inflammatory drugs). In severe cases or in patients who do not respond to nonsteroidal agents, a glucocorticoid such as prednisone, 20 mg three times daily for 7 to 10 days, may be necessary to reduce the inflammation. β-Adrenergic–blocking agents can be employed during the hyperthyroid phase to treat bothersome symptoms of hyperthyroidism.

T_4, 0.1 to 0.15 mg once daily, may be indicated during the hypothyroid phase of the illness if hypothyroid symptoms are present. T_4 therapy may also prevent exacerbations of inflammation due to elevated TSH levels.

Course and Prognosis

Subacute thyroiditis usually resolves completely and spontaneously over weeks or months. Occasionally, the disease may begin to resolve and then suddenly become worse, sometimes involving first one lobe of the thyroid gland and then the other (migrating or *creeping* thyroiditis). Exacerbations may occur when the FT_4 levels have fallen, the TSH level has risen, and the gland is starting to recover function. Rarely, the course may extend over several years, with repeated bouts of inflammatory disease. Ninety percent of patients recover without any sequelae. In about 10% of patients, permanent hypothyroidism ensues, and long-term T_4 therapy is necessary.

2. CHRONIC THYROIDITIS

Chronic thyroiditis (Hashimoto thyroiditis and lymphocytic thyroiditis) is the most common cause of hypothyroidism and goiter in the United States. It is certainly the major cause of goiter in children and young adults and is the cause of *idiopathic myxedema*, which represents an end stage of Hashimoto thyroiditis, with total destruction of the gland.

Etiology and Pathogenesis

Hashimoto thyroiditis is an immunologic disorder in which lymphocytes become sensitized to thyroidal antigens and autoantibodies are formed that react with these antigens (see thyroid autoimmunity, earlier). In Hashimoto thyroiditis, the three most important thyroid autoantibodies are: TG Ab, TPO Ab,

and *TSH-R*–blocking Ab. During the early phases of Hashimoto thyroiditis, TG Ab is markedly elevated, and TPO Ab is slightly elevated. Later, TG Ab may disappear, but TPO Ab is present for many years. Blocking Abs may be found in patients with atrophic thyroiditis and myxedema and, rarely, in mothers giving birth to infants with no detectable thyroid tissue (**athyreotic cretins**). The pathology of Hashimoto thyroiditis involves a heavy infiltration of lymphocytes totally destroying normal thyroidal architecture. Lymphoid follicles and germinal centers may be formed. The follicular epithelial cells are frequently enlarged and contain an eosinophilic cytoplasm laden with mitochondria (Hürthle cells). Destruction of the gland results in a fall in serum T_3 and FT_4 and a rise in TSH. Initially, TSH may maintain adequate hormonal synthesis by the development of thyroid enlargement or goiter, but often the gland fails, and hypothyroidism with or without goiter ensues.

Hashimoto thyroiditis is part of a spectrum of thyroid diseases that includes Graves disease at one end and idiopathic myxedema at the other (Figure 7–44). It is familial and may be associated with other autoimmune diseases, including pernicious anemia, adrenocortical insufficiency, idiopathic hypoparathyroidism, myasthenia gravis, and vitiligo. *Schmidt syndrome* consists of Hashimoto thyroiditis, idiopathic adrenal insufficiency, and, commonly, type 1 diabetes mellitus. This phenomenon has also been called the autoimmune polyglandular syndrome (see Chapter 2).

Clinical Features

A. Symptoms and signs Hashimoto thyroiditis usually presents with goiter in a patient who is euthyroid or has mild hypothyroidism. The female:male sex distribution is about 4:1. The process is painless, and the patient may be unaware of the goiter unless it becomes very large. Older patients may present with severe hypothyroidism with only a small, firm atrophic thyroid gland (idiopathic myxedema).

B. Laboratory findings There are multiple defects in iodine metabolism. RAIU may be high, normal, or low. Circulating thyroid hormone levels are usually normal or low, and if low, TSH will be elevated.

The most striking laboratory finding is the high titer of autoantibodies to thyroidal antigens in the serum. Serum tests for either TG or TPO Abs are positive in most patients with Hashimoto thyroiditis. Another diagnostic test that may be helpful is FNAB, which reveals lymphocytic infiltration as well as the presence of Hürthle cells.

Idiopathic myxedema	Hashimoto thyroiditis	Euthyroid Graves disease	Graves disease
Hypothyroid without goiter	Hypothyroid or euthyroid with goiter	Euthyroid with or without goiter	Hyperthyroid with goiter

FIGURE 7–44 Spectrum of autoimmune disease of the thyroid gland. The clinical manifestations of autoimmune disease of the thyroid gland range from idiopathic myxedema, through nontoxic goiter, to diffuse toxic goiter, or Graves disease. Progression of autoimmune disease from one form to another in the same patient can occasionally occur.

Differential Diagnosis

Hashimoto thyroiditis can be differentiated from other causes of nontoxic goiter by serum Ab studies and, if necessary, by FNAB.

Complications and Sequelae

The major complication of Hashimoto thyroiditis is progressive hypothyroidism. Most patients with Hashimoto thyroiditis initially have a small goiter and subclinical hypothyroidism, which is defined as normal serum levels of FT_4 and T_3, but mildly elevated serum TSH levels, usually less than 10 mU/L. This is in contrast to overt hypothyroidism, in which FT_4 levels are subnormal. Whether subclinical hypothyroidism is a significant health problem that warrants therapy is a matter of debate. Some patients may have mild symptoms of hypothyroidism as well as increased lipid levels and other risk factors for atherosclerotic cardiovascular disease. There may be progression to overt hypothyroidism over time, especially if serum levels of antithyroid Abs are high. On the other hand, most patients are asymptomatic, especially when TSH serum levels are less than 10 mU/L, and the link between atherosclerosis is still controversial.

One variant of Hashimoto thyroiditis has been termed **silent or painless thyroiditis**. It has a predilection for occurring in the postpartum period, developing in about 5% of postpartum women. In this setting it is called **postpartum thyroiditis**. Most patients have symptoms and signs of mild hyperthyroidism that may be difficult to distinguish from mild Graves disease. There are no eye findings, and unlike subacute thyroiditis, the thyroid is not tender to palpation. The serum FT_4 is elevated out of proportion to the serum T_3, typical of most forms of thyroiditis, when there is leakage of stored hormone into the bloodstream. The erythrocyte sedimentation rate is normal, which distinguishes it from subacute thyroiditis, and TPO Ab titers are elevated. Importantly, the 24-hour RAIU is low, rather than elevated, which readily distinguishes this condition from postpartum Graves disease. Silent thyroiditis may evolve with a triphasic course, similar to what is seen in subacute thyroiditis, with the hyperthyroid phase lasting 1 to 3 months, followed by a hypothyroid phase lasting several months as well. In postpartum thyroiditis, the hyperthyroid phase generally begins 3 to 4 months after delivery. Although recovery is the rule, about 25% of patients have permanent mild or subclinical hypothyroidism, which can progress with time to overt hypothyroidism. Long-term follow-up is required because permanent hypothyroidism can eventually develop in patients after many years. Also, recurrent episodes of silent thyroiditis can occur, and postpartum thyroiditis often develops following subsequent pregnancies.

Rarely, a patient with Hashimoto thyroiditis may develop lymphoma of the thyroid gland. Although the etiology of thyroid lymphoma is unknown, Hashimoto thyroiditis is a definite risk factor. It is possible that thyroid lymphoma may be the result of the expansion of an abnormal clone of an immortalized population of intrathyroidal lymphocytes. Thyroid lymphoma is characterized by rapid growth of the gland despite continued T_4 therapy; the diagnosis of lymphoma can be made by FNAB and immunocytochemical analysis, looking for a monoclonal population of lymphocytes, but sometimes requires surgical biopsy (see later).

Whether adenocarcinoma of the thyroid gland occurs more frequently in patients with Hashimoto thyroiditis is controversial, but the two diseases—chronic thyroiditis and carcinoma—can coexist in the same gland. Recent studies have shown that the presence of thyroid cancer in thyroid nodules is more frequent in patients whose serum TSH is higher, even when it is within the normal range. Cancer must be suspected when a solitary nodule or thyroid mass grows or fails to regress while the patient is receiving doses of T_4 that normalize or suppress the serum TSH. FNAB is critical in the differential diagnosis in this situation.

Treatment

The indications for treatment of Hashimoto thyroiditis are goiter or overt hypothyroidism; a patient with a positive thyroid Ab test alone does not require therapy. Surgery is rarely indicated for Hashimoto thyroiditis but occasionally is performed if a goiter does not regress and continues to cause compressive symptoms. The treatment of subclinical hypothyroidism is a matter of debate but is often instituted because of (1) mild symptoms; (2) dyslipidemia which could be ameliorated by T_4 therapy; and (3) positive antithyroid Ab titers, which predicts a higher chance of progression to overt hypothyroidism over time. Sufficient T_4 is given to normalize TSH and allow regression of the goiter.

The treatment of silent or postpartum thyroiditis varies with the patient's thyroid status. During the hyperthyroid phase, β-adrenergic–blocking drugs can be used to treat the symptoms of tremor, palpitations, and nervousness. T_4 can be used in the hypothyroid phase, but it is usually not needed, because symptoms are usually mild.

Course and Prognosis

Without treatment, Hashimoto thyroiditis usually progresses from goiter and subclinical hypothyroidism to overt hypothyroidism over many years. In severe cases, myxedema and myxedema coma may be the end result of untreated disease. With T_4 therapy, the goiter usually resolves, although not necessarily completely, and hypothyroid symptoms are reversed.

Because Hashimoto thyroiditis may be part of a syndrome of multiple autoimmune diseases (see Chapter 2), the patient should be monitored for other autoimmune diseases such as pernicious anemia, adrenal insufficiency, and type 1 diabetes mellitus. Patients with Hashimoto thyroiditis may also develop true Graves disease, occasionally with severe ophthalmopathy or dermopathy (see Figure 7–44). The chronic thyroiditis may blunt the severity of the thyrotoxicosis, so that the patient may present with eye or skin complications of Graves disease without marked thyrotoxicosis, a syndrome often called **euthyroid Graves disease**. The ophthalmopathy and dermopathy are treated as if thyrotoxic Graves disease were present.

3. OTHER FORMS OF THYROIDITIS

The thyroid gland may be subject to acute abscess formation in patients with septicemia or acute infective endocarditis or from local extension of a pharyngeal infection. Immunocompromised

hosts may develop opportunistic thyroidal infections, with involvement of organisms such as aspergillus, mycobacteria, and pneumocystis. Abscesses cause symptoms of pyogenic infection, with local pain and tenderness, swelling, and warmth and redness of the overlying skin. Needle aspiration confirms the diagnosis and identifies the organism. Treatment includes antibiotic therapy and occasionally incision and drainage. A thyroglossal duct cyst may become infected and present as acute suppurative thyroiditis. This too responds to antibiotic therapy and occasionally incision and drainage.

Riedel thyroiditis is associated with extensive fibrosis extending outside the gland and involving overlying muscle and surrounding tissues. Riedel struma (struma is an old term for the thyroid) presents as a stony-hard mass that must be differentiated from thyroid cancer. It is also associated with fibrosis in other parts of the body including the mediastinum and retroperitoneum. Many experts believe that Riedel thyroiditis is a part of systemic illness termed "Immunoglobulin (Ig) G4-related sclerosing disease (IgG4-RSD)" that is characterized by IgG4+ plasma cell infiltration and fibrosis in one or more organs, including the thyroid gland.

EFFECTS OF IONIZING RADIATION ON THE THYROID GLAND

Ionizing radiation can induce both acute and chronic thyroiditis. Thyroiditis may occur acutely in patients treated with large doses of radioiodine and may be associated with release of thyroid hormones and an acute thyrotoxic crisis. Such an occurrence is extremely rare, however, and pretreatment with antithyroid drugs to bring the patient to a euthyroid state prior to ^{131}I therapy should prevent this complication. Radioiodine therapy, which exposes the thyroid to a dosage of around 10,000 rads (cGy), is not associated with the development of thyroid cancer, presumably because the thyroid gland is largely destroyed by high doses of radiation. Thus, although the incidence of postradiation hypothyroidism is high, the incidence of thyroid cancer is extremely low.

External radiation was used many years ago for the treatment of respiratory problems in the newborn, thought to be due to thymic hyperplasia, and for the treatment of benign conditions such as severe acne and chronic tonsillitis or adenoiditis. This treatment has been associated with the later development of nodular goiter, hypothyroidism, or thyroid cancer. Fortunately, such therapy has not been used since the early 1960s. In addition, high doses of therapeutic radiation in children with Hodgkin disease or other cancers have also been associated with the development of thyroid cancer later in life. Almost all radiation-related thyroid cancers have been of the papillary type. In some parts of the world, radiation exposure from fallout from atomic bomb testing or a nuclear reactor accident has been associated with nodular thyroid disease and thyroid cancer. Although the overall frequency of thyroid carcinoma in irradiated patients is low, data from several large series suggest that the incidence of cancer in a patient who presents with a solitary cold nodule of the thyroid

gland and a history of therapeutic radiation of the head, neck, or chest is about 50%.

The most important episode of large-scale radiation-induced thyroid neoplasia was the Chernobyl disaster in April, 1986, at which time huge amounts of radioactive material, especially radioiodine, were released. As early as 4 years later, a striking increase in the incidence of thyroid nodules and thyroid cancer was noted in children in Gomel, an area in the Republic of Belarus that is close to Chernobyl and was heavily contaminated by the accident. A high proportion of the cancers arose in very young children and developed after a short latency period. The sex distribution was equal. Most of the cancers have been papillary carcinomas but they have been more aggressive than typical papillary cancer, with intraglandular, capsular, local, and lymph node invasion. A smaller release of radioiodine also occurred in 2011 in Fukushima, Japan after an earthquake and tsunami destroyed a nuclear power plant there. Thyroid ultrasound screening of children living in the area began in 2012, but thus far no increase in thyroid neoplasia in the exposed population has been reported.

Patients who have been exposed to ionizing radiation should be followed carefully for life. Annual studies should include physical examination of the neck for goiter or nodules and FT_4 or TSH determinations to rule out hypothyroidism. Periodic thyroid ultrasound may detect nodules that are not palpable. If a nodule is found and is greater than 1 cm in diameter, FNAB should be performed. If the nodule is malignant, the patient should have total thyroidectomy. If it is benign, follow-up with periodic thyroid ultrasound is recommended. If the nodule enlarges, repeat biopsy or surgery should be considered.

THYROID NODULES AND THYROID CANCER

Thyroid nodules are extremely common, particularly among women. The prevalence of palpable thyroid nodules in the United States has been estimated to be about 4% of the adult population, with a female-male ratio of 4:1. In young children, the prevalence is less than 1%; in persons aged 11 to 18 years, about 1.5%; and in persons over age 60, about 5%. In contrast to the relatively low prevalence of palpable nodules, thyroid nodules are detected on thyroid ultrasound in up to 50% of healthy individuals, especially middle-aged and older women.

Although thyroid nodules are common, thyroid cancer is a relatively rare condition, with an annual incidence of approximately 8.7 per 100,000 population. The incidence of diagnosed thyroid cancer has increased dramatically over the last two decades, in large part due to the discovery of thyroid nodules and cancers incidentally on imaging done for other reasons, including cervical CT scans and MRI, PET scans, and carotid Doppler testing. In 2017, there are expected to be approximately 57,000 new cases in the United States, compared to 37,000 in 2009. While the vast majority (90–95%) of thyroid nodules are benign, and it is important to identify those that are likely to be malignant in the most rational and cost-effective manner. In 95% of cases,

thyroid cancer presents as a nodule or lump in the thyroid, found on routine physical examination or incidentally on imaging for another reason. Occasionally, especially in children, enlarged cervical lymph nodes are the first sign of the disease, although on careful examination a small thyroid nodule can often be felt. Rarely, distant metastasis in lung or bone is the first sign of thyroid cancer.

1. BENIGN THYROID NODULES

Etiology

Benign conditions that can produce nodularity in the thyroid gland are listed in Table 7–10. They include focal areas of chronic thyroiditis; colloid-filled or hyperplastic cellular nodules within a multinodular goiter; a cyst involving thyroid tissue; rarely parathyroid tissue or thyroglossal duct remnants; and agenesis of one lobe of the thyroid, with hypertrophy of the other lobe presenting as a mass in the neck and mimicking a nodule. It is usually the left lobe of the thyroid that fails to develop, and the hypertrophy occurs in the right lobe. Finally, benign areas of hyperplasia and neoplasms in the thyroid, including follicular adenomas and Hürthle cell adenomas (also called oxyphil adenomas) present as thyroid nodules. Rare benign thyroidal lesions include teratomas, lipomas, and hemangiomas.

Differentiation of Benign and Malignant Lesions

Risk factors that predispose to benign or malignant disease are set forth in Table 7–11 and discussed later.

A. History   A family history of goiter suggests benign disease, as does residence in an area of endemic goiter. However, a family history of papillary or medullary carcinoma or a history of recent thyroid growth, hoarseness, dysphagia, or obstruction suggests cancer, as does exposure to ionizing radiation, as discussed earlier.

B. Clinical features   Clinical features associated with a lower risk of thyroid cancer include middle age, female sex, a soft thyroid nodule on physical examination, and the presence of a multinodular goiter. Individuals at higher risk of thyroid cancer include children, young adults, and older males. A solitary firm

TABLE 7–10   Etiology of benign thyroid nodules.

1. Focal thyroiditis
2. Dominant nodule in a multinodular goiter
3. Benign adenomas:
   a. Follicular
   b. Hürthle cell
4. Thyroid, parathyroid, or thyroglossal cysts
5. Agenesis of a thyroid lobe
6. Postsurgical remnant hyperplasia
7. Postradioiodine remnant hyperplasia
8. Rare: teratoma, lipoma, hemangioma

or dominant nodule that is clearly different from the rest of the gland signifies an increased risk of malignancy. Vocal cord paralysis, enlarged cervical lymph nodes, and suspected metastases are strongly suggestive of malignancy.

C. Serum factors   A serum TSH level should be the initial laboratory study in the evaluation of a thyroid nodule. The serum TSH level is an independent risk factor for thyroid cancer, with the risk of cancer rising progressively with serum TSH levels still within the normal range. For example, in one meta-analysis, the odds ratio for thyroid cancer in a nodule rose by 1.16 for each mU/L of TSH above 1 mU/L. Furthermore, higher serum TSH values have also been associated with more advanced degrees of thyroid cancer. If the serum TSH level is normal, which is the case for most patients, no further blood tests are needed. If the serum TSH is below normal, a radionuclide thyroid scan should be considered to see whether the nodule is hot or autonomously functioning (see later). In the presence of a firm thyroid gland or other clinical features of Hashimoto thyroiditis (eg, positive family history of hypothyroidism), serum anti-TG and anti-TPO Abs should be assessed. A high titer of thyroid autoantibodies in serum suggests chronic thyroiditis as the cause of thyroid enlargement and nodules, but does not rule out an associated malignancy. Measurement of serum calcitonin is not routinely advised. However, an elevated serum calcitonin in patients with a family history of medullary carcinoma strongly suggests the presence of medullary thyroid cancer. Elevated serum TG following total thyroidectomy for papillary or follicular thyroid cancer usually indicates residual or metastatic disease, but serum TG is not helpful in determining the nature of a thyroid nodule.

D. Imaging studies   Thyroid ultrasound has become the most important tool in the confirmation and differential diagnosis of thyroid nodules and provides considerably more information than radionuclide thyroid scans (see Figure 7–27). Ultrasound is used to confirm that a palpable neck mass is actually a thyroid nodule; to measure it establishes a nodule's size precisely and, hence, can be used for subsequent monitoring; it identifies specific sonographic features that are important in assessing the possibility of malignancy; and it often detects other nonpalpable nodules elsewhere in the gland that are clinically significant. In fact, the frequency of malignancy is the same whether a nodule is palpable or only detectable with imaging.

The sonographic features that are associated with a higher risk of malignancy include microcalcifications, irregular borders, and a "taller than wide" configuration (Table 7–12 and Figure 7–45). Other ultrasound characteristics, such as hyperechogenicity, a thin sonolucent rim ("halo") around the nodule, or a large cystic component favor a benign nodule (see Figure 7–45).

In patients with low serum TSH levels, radionuclide thyroid scanning with [123]Iodine or [99m]Technetium pertechnetate can be used to identify whether the nodule is hot or cold (ie, a nodule that takes up more [hot] or less [cold] radioactive material than surrounding thyroid tissue). Hot nodules are almost never

TABLE 7–11   Risk factors useful in distinguishing benign from malignant thyroid lesions.

	More Likely Benign	More Likely Malignant
History	Family history of benign goiter Residence in endemic goiter area	Family history of medullary cancer of thyroid Previous therapeutic irradiation of head or neck Recent growth of nodule Hoarseness, dysphagia, or obstruction
Physical characteristics	Older woman Soft nodule Multinodular goiter	Child, young adult, male Solitary, firm nodule clearly different from rest of gland (dominant nodule) Vocal cord paralysis, firm lymph nodes, distant metastases
Serum factors	High titer of thyroid autoantibodies	Elevated serum calcitonin
Scanning techniques		
^{123}I or ^{99m}TcO$_4$	Hot nodule	Cold nodule
Sonogram	Cyst (pure)	Solid or complex
Biopsy (needle)	Benign appearance on cytologic examination	Malignant or suggestion of malignancy
Levothyroxine therapy (TSH suppression for 3-6 mo)	Regression	No regression

malignant, and although 5% to 10% of cold nodules may be malignant, 90% to 95% of cold nodules are benign (Figure 7–46). On the other hand, thyroid scans are rarely helpful in patients with normal or elevated serum TSH levels.

E. Needle biopsy   FNAB of thyroid nodules to obtain cytological material for pathological examination is the principal test to distinguish benign from malignant lesions. Targeting thyroid nodules with suspicious ultrasound features for biopsy provides a higher yield of thyroid cancer than aspirating all nodules larger than 1 cm in diameter. Recent guidelines provide a framework for decision-making, which incorporates sonographic features plus nodule size (Table 7–13; see Figure 7–45). Purely cystic nodules without a mural component do not require biopsy, but the fluid could be aspirated if the nodule is causing pressure symptoms because of its size. However, cystic nodules often recur following aspiration.

The technique of FNAB is relatively simple, safe, reliable, and well tolerated. FNAB is now generally performed under sonographic guidance and definitely should be done so if the nodule

is nonpalpable, difficult to localize by palpation, or is cystic. FNAB separates thyroid nodules into six groups (Table 7–14 and Figure 7–47):

1. Nondiagnostic (insufficient).
2. Cytologically benign thyroid nodules (70%-80% of all biopsy specimens), which exclude cancer with a negative predictive value of 95% to 98%. These include adenomatoid nodules, colloid nodules, and Hashimoto thyroiditis.
3. Follicular lesion or atypia of undetermined significance (FLUS or AUS). This category includes nodules with nuclear atypia and those with mixed macro- and microfollicular architecture, those predominantly comprised of Hürthle cells.
4. Follicular neoplasm: This category includes microfollicular nodules and Hürthle cell nodules (Hürthle cells are large eosinophilic cells derived from follicular epithelium also called oxyphils).
5. Suspicious for malignancy: Specimen contains some cytologic features typically associated with cancer, but not enough to be confidently diagnosed as cancer.
6. Malignant: Cytologically malignant thyroid nodules (3%-5% of all biopsy specimens), which have a positive predictive value for cancer of 95% for all types of thyroid malignancies.

Nodules that are FLUS/AUS, or follicular neoplasms are grouped together as "indeterminate" or "suspicious." However, the majority of such nodules are benign.

Until recently, patients with indeterminate thyroid nodules on FNAB were sent to surgery for definitive diagnosis, which, in retrospect was often unnecessary, as the majority of indeterminate nodules are benign on histopathology. Recently, however, new tools have become available to assist in refining the diagnosis and to decrease the number of unnecessary surgeries. These "molecular tests" take advantage of recently acquired knowledge about the molecular genetics of thyroid neoplasia (Figure 7–48).

Gene point mutations and rearrangements are found in over 75% of thyroid cancers. For papillary thyroid cancer, mutations in genes coding for proteins in the MAPK signaling pathways,

FIGURE 7–45 American Thyroid Association categorization of sonographic features of thyroid nodules from benign/low suspicion to very high suspicion. (Reproduced with permission from Haugen BR Md, Alexander EK, Bible KC, et al. 2015 American Thyroid Association Management Guidelines for Adult Patients with Thyroid Nodules and Differentiated Thyroid Cancer. *Thyroid*. 2016 Jan;26(1):1-133.)

which regulate cell proliferation, differentiation, and survival, are of greatest importance. These include point mutations in BRAF (the V600E mutation), occurring in about 40% of papillary cancers, and *RAS* gene mutations (N-RAS, H-RAS, and K-RAS), which occur in about 20% of papillary cancers, in 30% to 40% of follicular cancers, and in approximately 20% of benign follicular adenomas. Additional genetic abnormalities seen in papillary thyroid cancers include gene rearrangements in which a portion of the *RET* gene, encoding a receptor tyrosine kinase not normally expressed in the thyroid, is linked to a portion of one of several unrelated genes at its 5′ end, producing a constitutively active chimeric RET receptor, collectively referred to as RET/PTC oncogenes. These oncogenic genetic changes are linked to radiation exposure. Finally, about 30% of follicular carcinomas, and a smaller fraction of follicular adenomas, contain a *PAX8/PPARγ* gene fusion, in which PAX8, a thyroid transcription factor is fused to the peroxisome proliferator-activated receptor, gamma isoform.

Based on these observations, biopsy specimens with indeterminate cytology can be subjected to further "molecular" analysis in an effort to increase the diagnostic accuracy and avoid unnecessary surgery. Two strategies are currently available commercially. In one method, using a so-called "mutation panel," DNA from the cells in the aspirate is analyzed for a specific mutations in BRAF and RAS, as well as for the presence of RET/PTC rearrangments and the PAX8/PPAR fusion. The presence of one of these genetic abnormalities is associated with a high-positive predictive value for malignancy (85%-90%). However, currently available mutation panels do not routinely detect mutations in 10% to 15% of patients with proven malignancy, and therefore a negative test does not confidently rule out the possibility of thyroid cancer. Newer mutational testing strategies, which include other genes in the panel, including TERT (telomerase reverse transcriptase) and the *TP53* tumor suppressor gene, may have even better sensitivity, but have not been validated.

The *mRNA* gene expression classifier is the other testing strategy that can be performed on indeterminate thyroid aspirates. In this method, the expression of a panel of 167 genes within the nodule is assessed by measuring mRNA levels using microarray technology. Validation studies of this method suggest that a
FIGURE 7-46 A functioning thyroid nodule in a patient with a palpable right lower pole thyroid nodule and a low serum TSH concentration but normal serum-Free T_4 and T_3 levels.

"benign" result is associated with a 94% to 95% negative predictive value, which would suggest that surgery can be postponed and the nodule observed. While most patients with suspicious gene classifier results opt for surgery, up to half of them will have a benign nodule on final pathology. Another strategy that is under development is the assessment of the expression of specific microRNAs (miRNAs) that are closely linked to thyroid malignancy.

Management of Thyroid Nodules

A decision tree for management of a thyroid nodule is presented in Figures 7–49A and 7–49B. A patient with a thyroid nodule, detected either on physical examination or imaging, should have a serum TSH and thyroid ultrasound performed. If the TSH is low, radionuclide thyroid scanning should be done to avoid performing FNAB in a patient with a hot nodule. If the serum TSH is normal or elevated, and ultrasound confirms the presence of one or more nodules, FNAB should be performed on those hypoechoic nodules that are larger than 1.0 to 1.5 cm, especially in the presence of other suspicious sonographic characteristics. If the nodule is cytologically malignant or if the reading is "suspicious for malignancy," the patient is generally referred for thyroid surgery unless there are other serious medical problems associated with high-operative risk and/or a prognosis much graver than thyroid cancer. If the nodule is cytologically benign and neither local compressive symptoms nor hyperthyroidism are present, only reassessment of nodule size in 6 to 18 months by physical examination and/or ultrasound is required. If the nodule grows, defined as an increase of 20% or more in two of three dimensions, repeat FNAB and cytological examination may be indicated to verify the benign diagnosis. However, in this situation, the original benign results are confirmed 98% to 99% of the time.

In patients with cytologically indeterminate nodules, a radionuclide scan may be obtained if the serum TSH is at the lower end of the normal range. If the scan reveals the nodule to be hot (ie, functioning and suppressing the remainder of the gland), the patient can be observed to detect future overt hyperthyroidism. If the lesion is cold and in all other situations where the serum TSH is within the reference range, both surgery (a diagnostic

TABLE 7–13 Sonographic patterns, estimated risk of malignancy, and fine-needle aspiration guidance for thyroid nodules.

Sonographic Pattern	Sonographic Features	Estimated Risk of Malignancy (%)	Size Cutoff for Biopsy
High suspicion	Solid hypoechoic nodule or solid hypoechoic component of a partially cystic nodule with one or more of the following features: irregular margins (infiltrative, microlobulated), microcalcifications, taller than wide shape, rim calcifications with small extrusive soft tissue component, evidence of ETE	>70-90	Recommend FNA at ≥1 cm
Intermediate suspicion	Hypoechoic solid nodule with smooth margins without microcalcifications, ETE, or taller than wide shape	10-20	Recommend FNA at ≥1 cm
Low suspicion 5-10	Isoechoic or hyperechoic solid nodule, or partially cystic nodule with eccentric solid areas, without microcalcification, irregular margin or ETE, or taller than wide shape	5-10	Recommend FNA at ≥1.5 cm
Very low suspicion	Spongiform or partially cystic nodules without any of the sonographic features described in low, intermediate, or high suspicion patterns	<3	Consider FNA at ≥2 cm Observation without FNA is also a reasonable option
Benign	Purely cystic nodules (no solid component)	<1	No biopsy

Abbreviation: ETE, Extrathyroidal Extension.

FIGURE 7-48 Signaling pathways for thyroid cell proliferation, differentiation, and survival. Several pathways are involved in propagation of signals from various cell membrane receptor tyrosine kinases into the nucleus. They regulate multiple cell processes including proliferation, differentiation and survival. Activation of the MAPK pathway by oncogenic stimuli such as mutated BRAF, RAS or the chimeric fusion proteins RET/PTC, and TRK is a common tumor initiating event in well-differentiated papillary carcinoma and in some follicular carcinomas. Mutations involving the effectors of the PI3K–AKT pathway such as the PI3K subunit PIK3CA, AKT1, and PTEN are found more frequently in follicular carcinomas and in less differentiated types of thyroid cancer. (Reproduced with permission from Nikiforov YE, Nikiforova MN. Molecular genetics and diagnosis of thyroid cancer. *Nat Rev Endocrinol*. 2011 Aug 30;7(10):569-580.)

lobectomy) and molecular testing are reasonable options, depending on patient preference, other clinical features such as patient age, and the nodule's size and sonographic features. On the other hand, if an indeterminate nodule is less than 1 cm in diameter, observation with serial sonography is reasonable, with surgery only if the lesion grows.

2. THYROID CANCER

Pathology

The types and approximate frequency of malignant thyroid tumors are listed in Table 7–15.

A. Papillary carcinoma Papillary carcinoma of the thyroid gland typically presents as a nodule that is firm and solid on thyroid ultrasound, sometimes with internal calcifications. In multinodular goiter, the cancer is usually a dominant nodule—larger, firmer, and/or with ultrasound characteristics more suspicious than other nodules in the gland. About 10% of papillary carcinomas, especially in children, present with enlarged cervical nodes. Careful examination then often also reveals a nodule in the thyroid. Sometimes, there is hemorrhage, necrosis, and cyst formation in the malignant nodule, but on thyroid ultrasound of these lesions, a defined solid component is an indication for FNAB of this nodule component. Finally, papillary carcinoma may be found incidentally as a microscopic focus of cancer in a gland removed for other reasons, such as another indeterminate nodule, multinodular goiter, or Graves disease. Microscopically, papillary cancer typically consists of single layers of thyroid cells arranged in vascular stalks, with papillary projections extending into microscopic cyst-like spaces. The nuclei of the cells are large and pale and frequently contain clear, glassy intranuclear inclusion bodies. About 40% of papillary carcinomas form laminated calcified spheres—often at the tip of a papillary projection—called psammoma bodies. Most papillary thyroid cancers grow slowly and remain confined to the thyroid gland and local lymph nodes. However, these cancers can exhibit intraglandular metastasis and lymph node spread. In some children with papillary thyroid cancer, there are extensive lymph node and pulmonary micrometastases. In older patients, papillary cancer can be aggressive and invade locally into adjacent muscles, nerves, and trachea. In later stages, these tumors may spread to the lung, bone, brain, and other organs. Death is usually due to local disease, with invasion of deep tissues in the neck; less commonly, death may be due to extensive distant metastases. In some older patients, a longstanding, slowly growing papillary carcinoma begins to grow rapidly and converts to undifferentiated or anaplastic carcinoma.

Most papillary carcinomas secrete TG, which can be used as a marker for recurrence or metastasis of the cancer. Some papillary cancers concentrate radioiodine, albeit less efficiently than normal thyroid tissue. In such patients, radioiodine is an effective tool for identification and treatment of extrathyroidal disease.

B. Follicular carcinoma Follicular carcinoma is characterized histologically by the presence of small follicles with poor colloid formation. Follicular carcinoma is distinguished from benign follicular adenoma microscopically by the presence of capsular and/or vascular invasion within the tumor capsule. When only the capsule is involved, follicular cancer is categorized as minimally invasive, a tumor that typically has an indolent course similar to low-grade papillary cancers. When capsular blood vessels are also invaded, follicular cancers are categorized as invasive and have the potential for distant metastatic spread to bone, lung, and other sites. These tumors often retain the ability to concentrate radioactive iodine, form TG, and, rarely, synthesize T_3 and T_4. This may render these tumors responsive to radioactive iodine therapy. When death occurs, it is attributable to local extension or distant metastases with extensive involvement of bone, lungs, and viscera.

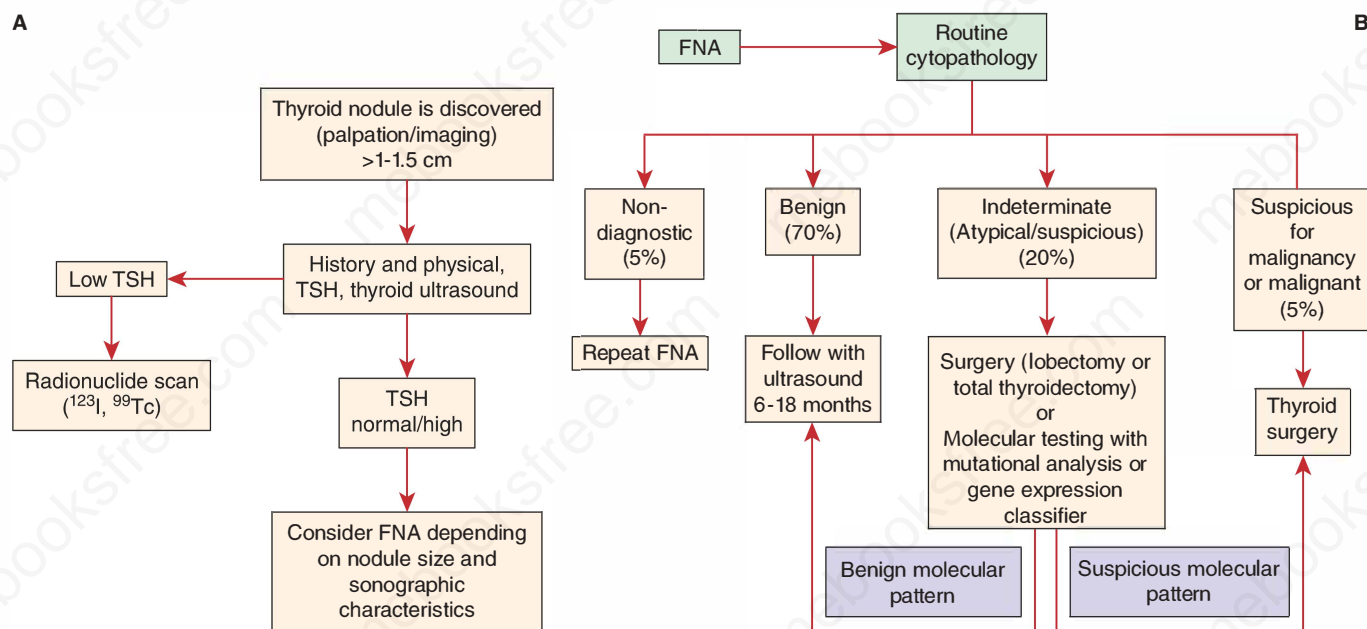
A variant of follicular carcinoma is the **Hürthle cell or oxyphil cell carcinoma**, characterized by large individual cells with


FIGURE 7-49 **A.** Decision matrix for the initial evaluation of a thyroid nodule. All patients with suspected thyroid nodules should have serum TSH measured and a thyroid ultrasound to document the nodule and its sonographic characteristics. If the serum TSH is low, a radionuclide thyroid scan should be considered. **B.** Decision matrix following thyroid fine-needle aspiration (FNA). Nodules that are indeterminate can be managed with surgery (lobectomy or thyroidectomy) or additional evaluation with molecular testing can be undertaken.

pink-staining cytoplasm filled with mitochondria. They behave like follicular cancer except that they rarely take up radioiodine.

C. Medullary carcinoma   Medullary thyroid cancer is a disease of the C cells (parafollicular cells) derived from the ultimobranchial body. These cells are capable of secreting calcitonin, carcinoembryonic antigen (CEA), histaminase, prostaglandins, serotonin, and other peptides (see Chapters 8 and 22). Microscopically, these tumors consist of sheets of cells separated by a pink-staining substance that stains with Congo red, typical of amyloid.

Medullary thyroid carcinoma is typically more aggressive than papillary or follicular carcinoma, extending locally to cervical lymph nodes and into surrounding tissues. It may also invade lymphatics and blood vessels and metastasize to lungs, liver, and other viscera. The calcitonin and CEA secreted by the tumor are clinically useful markers for diagnosis and follow-up.

TABLE 7–15 Approximate frequency of malignant thyroid tumors.

Papillary carcinoma (including mixed papillary and follicular)	80%
Follicular carcinoma (including Hûrthle cell carcinoma)	10%
Medullary carcinoma	5%
Undifferentiated (anaplastic) carcinomas	3%
Miscellaneous (including lymphoma, fibrosarcoma, squamous cell carcinoma, malignant hemangioendothelioma, teratomas, and metastatic carcinomas)	1%

Eighty percent of medullary carcinomas are sporadic, and the remainder are familial. There are three familial patterns: (1) familial medullary cancer without associated endocrine disease; (2) multiple endocrine neoplasia 2A (MEN 2A), consisting of medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism; and (3) MEN 2B, consisting of medullary thyroid cancer, pheochromocytoma, multiple mucosal neuromas, as well as intestinal ganglioneuromatosis. There is also a variant of MEN 2A with cutaneous lichen amyloidosis, a pruritic skin lesion located on the upper back. These familial syndromes are due to *RET* protooncogene mutations, most commonly in exons 10, 11, or 16 (see later, Chapters 8 and 22).

If medullary thyroid cancer is diagnosed by FNAB or at surgery, it is essential that the patient be screened for one of the familial medullary thyroid carcinoma syndromes by DNA analysis for mutations in the *RET* protooncogene. If screening is negative, the tumor is almost certainly sporadic, and no investigation of family members is required. If a mutation is found, family members should then be screened.

D. Undifferentiated (anaplastic) carcinoma   Undifferentiated thyroid gland cancer include small cell, giant cell, and spindle cell carcinomas. They usually occur in older patients, who often have a long history of goiter with sudden gland enlargement over weeks or months, causing pain, dysphagia, hoarseness, and/or dyspnea. Death from aggressive local extension and metastatic disease typically occurs within 6 to 36 months. These tumors are very resistant to all currently available therapies.

E. Miscellaneous types

1. **Lymphoma**—Thyroid lymphoma may develop as part of a generalized lymphoma or may be primary in the thyroid gland. Primary thyroid lymphoma usually develops in patients with longstanding Hashimoto thyroiditis. It may be difficult to distinguish from chronic thyroiditis histologically. There is a monoclonal lymphocyte population with invasion of thyroid follicles and blood vessel walls. If there is no systemic involvement, the tumor may respond dramatically to combined radiation and chemotherapy.

2. **Cancer metastatic to the thyroid**—Systemic cancers can metastasize to the thyroid gland. Common primary cancers responsible for these metastases include breast, kidney, lung carcinomas, and malignant melanoma. The primary site of involvement is usually obvious. Occasionally, the diagnosis is made by biopsy of an enlarging cold thyroid nodule. The prognosis is that of the primary tumor.

F. Molecular biology of thyroid neoplasms   Extensive studies have revealed frequent gene mutations in both benign and malignant thyroid neoplasms (Figures 7–48 and 7–50). Activating mutations in the *gsp* oncogene, encoding Gsα or the TSH receptor in thyroid cells have been associated with increased growth and function in benign hot or toxic thyroid nodules. Activating mutations of the *RAS* oncogene and loss of function of *PTEN* a tumor suppressor gene, are common in benign follicular adenomas. Progression to follicular carcinoma may occur after another genetic event involving a chromosomal translocation forming a fusion gene between the thyroid transcription factor *PAX8* gene and the *PPARγ* gene (*PAX8-PPARγ*). Further loss of the suppressor gene *P53* may allow progression to an anaplastic carcinoma. Papillary cancer is likely caused by mutations in genes in the MAP kinase–signaling pathway, especially *BRAF*. Subsequent loss of *P53* suppressor gene may allow progression to anaplastic carcinoma. As noted earlier, activating

mutations of the *RET* protooncogene on chromosome 10 have been shown to be associated with MEN 2A, MEN 2B, and familial medullary thyroid cancer. About 85% to 90% of the mutations found in MEN 2A and familial medullary thyroid cancer occur in exons 10 and 11, whereas about 95% of the mutations associated with MEN 2B are found in codon 918 in exon 16 of the *RET* oncogene. These mutations can be demonstrated in DNA from peripheral white blood cells utilizing the polymerase chain reaction and DNA sequencing. In patients with MEN 2 or familial medullary thyroid cancer who do not demonstrate a mutation in *RET*, family unit linkage analysis may be used to identify gene carriers. Thus, families can be screened for the carrier state, and early diagnosis and treatment can be instituted (Figure 7–51). Somatic mutations in the *RET* oncogene occur in about 30% of sporadic medullary thyroid cancer cells, but this does not occur in white blood cells and does not represent a germline mutation (see also Chapter 22).

Management of Thyroid Cancer (Figure 7–52)

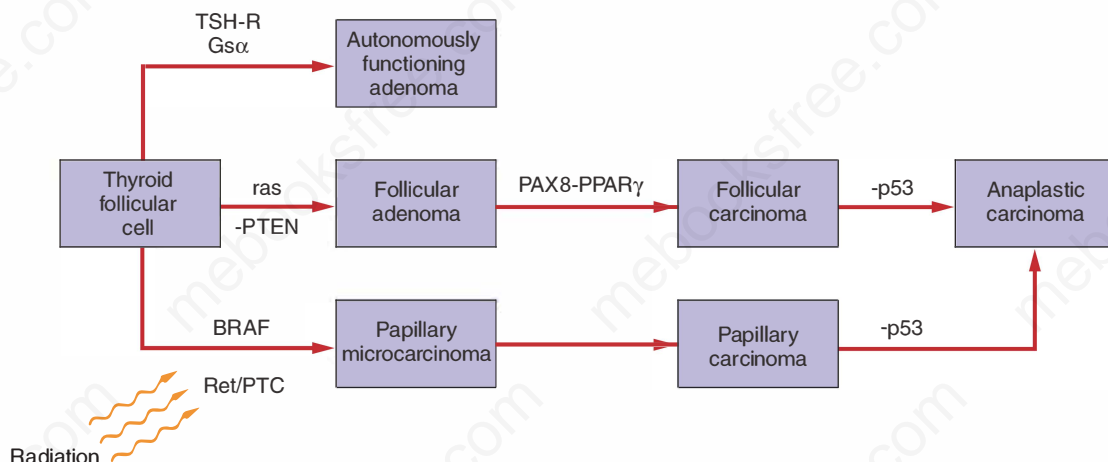
A. Papillary and follicular carcinoma: staging and treatment   Staging of cancer usually relies on the tumor-nodes-metastases (TNM) system for staging thyroid cancer (Table 7–16). Papillary and follicular thyroid carcinomas are grouped together, and staging is related to the age of the patient at the time of diagnosis. The cause-specific 5-year mortality rates are for stage 1, 0%; stage 2, 1%; stage 3, 5%; and stage 4, 77%. The TNM system may underestimate the risk of recurrence and death in younger patients with aggressive disease. Also, the TNM system was designed to predict cancer-related mortality, not the risk of recurrence. Since most patients with differentiated thyroid cancer survive their illness, but their course may be punctuated with recurrent disease over time that may require


FIGURE 7–50 Molecular defects associated with development and progression of human thyroid neoplasms. The hypothetical role of specific mutational events in thyroid tumorigenesis is inferred from their prevalence in the various thyroid tumor phenotypes (see text for details). (Reproduced with permission from Fagin JA. Genetic basis of endocrine disease 3: molecular defects in thyroid gland neoplasia. *J Clin Endocrinol Metab.* 1992 Dec;75(6):1398-1400.)

therapy with additional surgery or radioiodine, the American Thyroid Association has developed a validated risk stratified system that is able to predict recurrent disease (Table 7–17).

Because both papillary and follicular cancers arise from thyroid epithelial cells and sometimes respond to TSH and concentrate iodine, they are grouped together as **differentiated thyroid cancers**. These patients may be classified loosely into low-risk and high-risk groups. The low-risk group includes patients under age 45 with primary lesions under 4 cm and no evidence of intra- or extraglandular spread. For these patients, lobectomy is probably adequate therapy. All other patients should be considered to be at higher risk, and for these, total thyroidectomy and—if there is preoperative or intraoperative evidence of lymphatic spread—central compartment neck dissection are indicated. In the absence of evidence of lymphatic spread, prophylactic neck dissection may not be necessary, but can be considered for larger tumors (>4 cm).

For some low-risk patients, especially those under age 45 with large or numerous lymph node metastases, and all high-risk patients, postoperative radioiodine ablation of residual thyroid

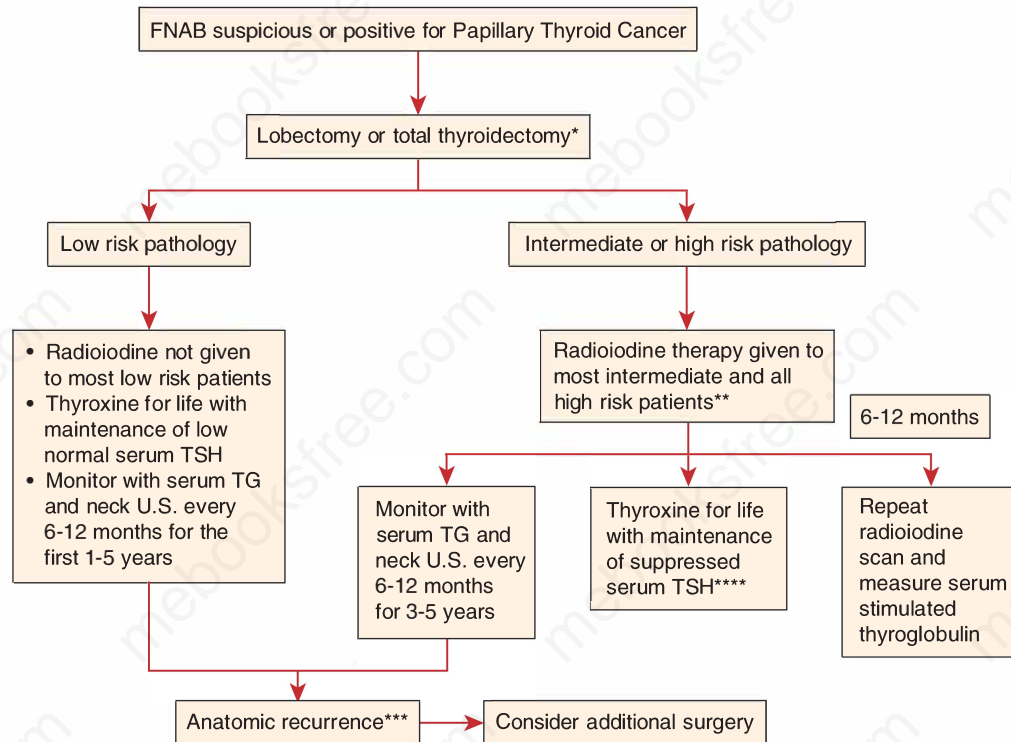
remnant is recommended as adjuvant therapy in an effort to decrease the likelihood of recurrent disease. To achieve maximal uptake of radioiodine into the remnant, an elevated serum TSH level is required. This can be achieved using injections of recombinant human TSH (rhTSH) given to patients in the euthyroid state. Alternatively, TSH stimulation can be achieved by withdrawing the patient from T_4 therapy, which causes transient clinical hypothyroidism. If the latter method is employed, T_3 is often prescribed temporarily at a dose of 25 to 50 µg daily in divided doses for 2 to 4 weeks; the medication is then stopped for 2 weeks, and, because of its 1-day half-life, patients quickly become hypothyroid prior to radioiodine therapy. In general, rhTSH is preferred, since clinical hypothyroidism is avoided and whole body radiation exposure is lower as the radioiodine is cleared from the body more rapidly because renal function is preserved. Regardless of how the patient achieves an elevated serum TSH level, a low-iodine diet is prescribed for 1 to 2 weeks to enhance uptake of the radioisotope. Following either rhTSH stimulation or thyroid hormone withdrawal, the serum TG level is


FIGURE 7–52 Decision matrix for the management of papillary or follicular thyroid cancer based on 2015 American Thyroid Association Guidelines. (Data from Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association Management Guidelines for Adult Patients with Thyroid Nodules and Differentiated Thyroid Cancer. *Thyroid*. 2016 Jan;26(1):1-133.)

*Either lobectomy or total thyroidectomy is acceptable for tumors <4 cm in diameter. The decision to perform a total thyroidectomy may take into account disease on the contralateral side, the plan to administer postoperative radioiodine, and patient preference.

**Radioiodine therapy has not been shown to decrease recurrence rates in low-risk patients. The data on recurrence rates are equivocal in intermediate risk patients, and show benefit in high-risk patients.

***Anatomic recurrences typically involve disease in the cervical nodes. Treatment options include surgery or local ablative measures (eg, ethanol ablation), or observation for small (<1 cm) nodes, especially in the lateral compartments.

****Suppression of the serum TSH with levothyroxine has been shown to be of more benefit in patients with higher stages of disease. In older patients with thyroid cancer, the benefits of TSH suppression and iatrogenic thyrotoxicosis have to be balanced against a risk of atrial fibrillation and bone loss in postmenopausal women.

determined, and the patient is scanned 24 to 72 hours after a low dose of radioiodine (ie, 1-4 mCi of ^{131}I or 1-2 mCi ^{123}I). If there is evidence of residual RAIU in the neck or elsewhere radioactive iodine (^{131}I) is administered in a dose of 30 to 100 mCi, depending on the size and invasiveness of the primary tumor. A whole body radioiodine scan is then repeated 4 to 7 days later (called a **posttherapy scan**) to be sure no additional areas of RAIU are revealed. Nine to 12 months later, rhTSH is administered or thyroid hormone therapy is withdrawn, and a radioiodine scan and serum TG are repeated to document ablation of all functioning thyroid tissue. An undetectable serum TG level, at a time when the serum TSH is elevated, is the most sensitive evidence that all thyroid tissue has been eradicated. Indeed, a repeat whole body radioiodine scan may not be needed in low-risk patients. For the first year, patients are typically maintained on doses of T_4 that are adequate to suppress serum TSH to levels that are subnormal. Once it has been established that the patient is free of disease, the dose of T_4 can be increased to allow the serum TSH to rise into the low-normal range (0.3-2 mU/L).

rhTSH, rather than thyroid hormone withdrawal, is usually employed for follow-up evaluations. When using rhTSH, the patient continues to take his T_4, avoiding the adverse effects of hypothyroidism. If the patient's TSH-stimulated serum TG is less than 1 ng/mL and the whole body radioiodine scan, if obtained, is negative, the patient is likely free of disease. On the other hand, if the serum TG concentration rises above 2 ng/mL and/or if the radioiodine scan is positive, the patient is likely to have either persistent thyroid remnant tissue or residual thyroid cancer. Neck sonography, CT, MRI, or PET scanning should be considered in this circumstance to look for evidence of residual thyroid cancer. If disease is localized anatomically and proven to be thyroid cancer, additional surgery may be warranted. If the stimulated TG is greater than 20 ng/mL and other anatomic imaging studies are negative, some experts recommend empiric radioiodine therapy because of the high suspicion of residual disease that might then be visualized on the posttreatment scan.

Follow-up at intervals of 6 to 12 months should include careful examination of the neck, sometimes including neck ultrasound,

TABLE 7-16 Tumor (T), lymph node (N), and distant metastasis (M) classification and staging of thyroid cancer.

Definition of Primary Tumor (T)

Papillary, Follicular, and Hurthle Cell Thyroid Carcinoma

T Category	T Criteria
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤2 cm in greatest dimension limited to the thyroid
T1a	Tumor ≤1 cm in greatest dimension limited to the thyroid
T1b	Tumor >1 cm but ≤2 cm in greatest dimension limited to the thyroid
T2	Tumor >2 cm but ≤4 cm in greatest dimension limited to the thyroid
T3	Tumor >4 cm limited to the thyroid, or gross extrathyroidal extension invading only strap muscles
T3a	Tumor >4 cm limited to the thyroid
T3b	Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumor of any size
T4	Includes gross extrathyroidal extension
T4a	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
T4b	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size

Note: All categories may be subdivided: (s) solitary tumor and (m) multifocal tumor (the largest tumor determines the classification).

Definition of Distant Metastasis (M)

M Category	M Criteria
M0	No distant metastasis
M1	Distant metastasis

Definition of Regional Lymph Node (N)

N Category	N Criteria
NX	Regional lymph nodes cannot be assessed
N0	No evidence of locoregional lymph node metastasis
N0a	One or more cytologically or histologically confirmed benign lymph nodes
N0b	No radiologic or clinical evidence of locoregional lymph node metastasis
N1	Metastasis to regional nodes
N1a	Metastasis to level VI or VII (pretracheal, paratracheal, or prelaryngeal/Delphian, or upper mediastinal) lymph nodes. This can be unilateral or bilateral disease
N1b	Metastasis to unilateral, bilateral, or contralateral lateral neck lymph nodes (levels I, II, III, IV, or V) or retropharyngeal lymph nodes

AJCC Prognostic Stage Groups

Differentiated

When age at Diagnosis is...	And T is...	And N is...	And M is...	Then the Stage Group is...
<55 years	Any T	Any N	M0	I
<55 years	Any T	Any N	M1	II
≥55 years	T1	N0/NX	M0	I
≥55 years	T1	N1	M0	II
≥55 years	T2	N0/NX	M0	I
≥55 years	T2	N1	M0	II
≥55 years	T3a/T3b	Any N	M0	II
≥55 years	T4a	Any N	M0	III
≥55 years	T4b	Any N	M0	IVA
≥55 years	Any T	Any N	M1	IVB

looking for recurrent masses, which typically develop in ipsilateral cervical nodes. If an abnormal lymph node is discovered, FNAB is indicated to confirm or rule out cancer depending on the size and location of the abnormal node(s). The patient's serum TSH should be checked to be certain it is adequately suppressed. The serum TG should be periodically assessed to be certain it is undetectable. A rise in serum TG to detectable levels while TSH is suppressed suggests tumor recurrence, and imaging studies such as neck ultrasound, CT, and MRI are necessary. PET scanning may also be useful to localize residual disease, especially in patients with very high serum TG levels (>20 ng/mL) when conventional imaging studies have been unrevealing.

TG autoantibodies present in 20% of patients interfere with accurate measurement of TG in radioimmunometric assays which are used in the majority of commercial laboratories and hospitals, causing falsely low values. Patients with TG autoantibodies must be followed with periodic imaging studies, such as thyroid ultrasound or CT scan.

The patient with a rising TG and a negative ^{131}I scan presents a common and difficult problem. Serial anatomic imaging, especially with cervical sonography, can sometimes identify the site of residual cervical disease. Administration of large empiric ^{131}I doses has not been shown to be of significant benefit. For patients with noniodine-avid metastatic disease that is progressive, recent studies have shown that several kinase–inhibiting drugs, including sorafenib and lenvatinib, can be effective in halting further tumor growth for 1 to 2 years. The kinases involved include the vascular endothelial growth factor receptor (VEGF) family, RET, and

TABLE 7–17 ATA system for estimating risk of thyroid cancer recurrence.*

LOW RISK (1-10% recurrence rate)
Papillary thyroid cancer with all of the following present:
- No local or distant metastases
- All macroscopic tumor has been resected
- No invasion of locoregional tissues
- Tumor does not have aggressive histology (eg, tall cell, insular, columnar cell carcinoma, Hürthle cell carcinoma, follicular thyroid cancer, hobnail variant)
- No vascular invasion
- No radioiodine uptake outside the thyroid bed on the post-treatment scan, if done
- Clinical N0 or ≤5 pathologic N1 micrometastases (<0.2 cm in largest dimension)
- Intrathyroidal, encapsulated follicular variant of papillary thyroid cancer*
- Intrathyroidal, well-differentiated follicular thyroid cancer with capsular invasion and no or minimal (<4 foci) vascular invasion
- Intrathyroidal, papillary microcarcinoma, unifocal or multifocal, including BRAF V600E mutated (if known)

INTERMEDIATE RISK (10-40% recurrence rate)
- Microscopic invasion into the perithyroidal soft tissues
- Cervical lymph node metastases or ^{131}I uptake outside the thyroid bed on the post-treatment scan done after thyroid remnant ablation
- Tumor with aggressive histology or vascular invasion (eg, tall cell, insular, columnar cell carcinoma, Hürthle cell carcinoma, follicular thyroid cancer, hobnail variant)
- Clinical N1 or >5 pathologic N1 with all involved lymph nodes <3 cm in largest dimension*
- Multifocal papillary thyroid microcarcinoma with extrathyroidal extension and BRAF V600E mutated (if known)*

HIGH RISK (>40% recurrence rate)
- Macroscopic tumor invasion
- Incomplete tumor resection with gross residual disease
- Distant metastases
- Postoperative serum thyroglobulin suggestive of distant metastases
- Pathologic N1 with any metastatic lymph node ≥3 in largest dimension*
- Follicular thyroid cancer with extensive vascular invasion (>4 foci of vascular invasion)

Reproduced with permission from Haugen BR Md, Alexander EK, Bible KC, et al. 2015 American Thyroid Association Management Guidelines for Adult Patients with Thyroid Nodules and Differentiated Thyroid Cancer. *Thyroid*. 2016 Jan;26(1):1-133.

BRAF. For patients with bone or brain metastases, combined external radiation and ^{131}I therapy may be effective.

B. Differentiated thyroid cancer: course and prognosis

An optimal outcome is dependent on adequate therapy. There has been controversy over the extent of initial surgery for papillary and follicular thyroid cancer. As noted earlier, lesions under 4 cm with no evidence of local or distant metastases (T1, N0, M0) can probably be treated with lobectomy alone. However, in all other groups, total thyroidectomy and modified regional neck dissection (if gross evidence of spread is noted at the time of surgery) is indicated for two reasons: (1) it removes all local disease, and (2) it sets the stage for ^{131}I therapy and follow-up utilizing serum TG measurements. Total or near-total thyroidectomy must be performed by an experienced thyroid surgeon to minimize the complications of surgery.

A second factor in survival is the use of radioiodine for ablation of residual thyroid tissue after thyroidectomy in Stages 3 and 4 patients and the treatment of residual or recurrent disease. Low doses of 30 to 50 mCi ^{131}I are used to ablate residual thyroid tissue, but larger doses of 100 to 200 mCi are necessary for the treatment of invasive or metastatic disease. Acute adverse effects of the larger doses include radiation sickness, sialadenitis, gastritis, and transient oligospermia. Cumulative doses of ^{131}I above 500 mCi may be associated with transient infertility in females and azoospermia in males, pancytopenia in about 4% of patients, and leukemia in about 0.3%. Radiation pneumonitis may occur in patients with diffuse pulmonary metastases, but this is minimized by utilization of high-dose treatment no more than once a year. There is no evidence that radioiodine therapy improves the outcome in younger patients with low-risk disease, but it may decrease recurrence rates and overall survival in older patients and those with higher risk disease.

A third factor in survival is the adequate use of TSH suppression therapy. T_4 in a dose of 2.2 μg/kg/d (1 μg/lb/d) usually suppresses TSH to 0.1 mU/L or less, which removes a major growth factor for papillary or follicular thyroid cancer. Low-risk patients do not require suppressive doses of thyroid hormone, but larger doses are indicated in intermediate and higher risk patients. High-dose T_4 therapy is not without risk: there may be angina, tachycardia, or heart failure in older patients or tachycardia and nervousness in younger patients. In addition, there is an increased risk of osteoporosis in postmenopausal women. Calcium supplementation and bisphosphonate therapy may prevent bone loss in these patients, but the treatment program must be individualized.

C. Medullary carcinoma

Early and adequate initial thyroidectomy and cervical node dissection is the best therapy for medullary cancer. Once the disease has metastasized, it is very difficult to control, though the more favorable tumor types often progress very slowly. Patients with medullary cancer should be followed postoperatively with periodic measurement of serum markers (eg, calcitonin and CEA) that indicate residual disease. Family members of patients with an *RET* oncogene mutation should be screened for the mutation as noted earlier (see Figure 7–51). If a patient has a persistently elevated serum calcitonin concentration after total thyroidectomy and regional node dissection, neck ultrasound, CT, MRI, and/or selective venous catheterization and sampling for serum calcitonin may reveal the location of the metastases. Metastatic foci of medullary cancer may also be revealed by PET, indium-labeled somatostatin (octreotide), or sestamibi scans. If these studies fail to localize the lesion (as is often the case), the patient must be followed until the metastatic lesions become evident by physical examination or imaging studies. External x-ray therapy may be useful in the treatment of some metastatic lesions. Chemotherapy with tyrosine kinase inhibitors, especially the *RET* inhibitor vandetanib has recently been shown to be highly effective in

preventing disease progression in many patients with medullary cancer. Metastatic medullary cancer cannot be treated with ^{131}I, and TSH-suppressive doses of T_4 are not required.

Medullary thyroid cancer is most aggressive in patients with MEN 2B, less aggressive in the sporadic type, and least aggressive in MEN 2A and familial medullary thyroid cancer.

D. Anaplastic carcinoma   Anaplastic carcinoma of the thyroid has a very poor prognosis. Treatment consists of minimal surgery to biopsy the tumor and establish the diagnosis, and sometimes to debulk the tumor and prevent tracheal compression. Standard treatment incorporates combined radiotherapy and chemotherapy with doxorubicin, which is sometimes combined with other agents. Occasionally, patients have prolonged survival, but most succumb to their disease within 1 year.

CELLULAR AND EXTRACELLULAR CALCIUM METABOLISM

The calcium ion plays a critical role in intracellular and extracellular events in human physiology. Extracellular calcium levels in humans are tightly regulated within a narrow physiologic range to provide for proper functioning of many tissues: excitation-contraction coupling in the heart and other muscles, synaptic transmission and other functions of the nervous system, platelet aggregation, coagulation, and secretion of hormones and other regulators by exocytosis. The level of intracellular calcium is also tightly controlled, at levels about 10,000-fold lower than extracellular calcium, in order for calcium to serve as an intracellular

TABLE 8–1 Calcium concentrations in body fluids.

Total serum calcium	8.5-10.5 mg/dL (2.1-2.6 mmol/L)
Ionized calcium	4.4-5.2 mg/dL (1.1-1.3 mmol/L)
Protein-bound calcium	4.0-4.6 mg/dL (0.9-1.1 mmol/L)
Complexed calcium	0.7 mg/dL (0.18 mmol/L)
Intracellular free calcium	0.00018 mmol/L (180 nmol/L)

second messenger in the regulation of cell division, muscle contractility, cell motility, membrane trafficking, and secretion.

It is the concentration of ionized calcium ($[Ca^{2+}]$) that is regulated in the extracellular fluid. The ionized calcium concentration averages 1.25 ± 0.07 mmol/L (Table 8–1). However, only about 50% of the total calcium in serum and other extracellular fluids is present in the ionized form. The remainder is bound to albumin (about 40%) or complexed with anions such as phosphate and citrate (about 10%). The protein-bound and complexed fractions of serum calcium are metabolically inert and are not regulated by hormones; only the ionized $[Ca^{2+}]$ serves a regulatory role, and only this fraction is itself regulated by the calciotropic hormones parathyroid hormone (PTH) and 1,25 dihydroxyvitamin D [$1,25(OH)_2D$]. Large increases in the serum concentrations of phosphate or citrate can, however, by mass action, markedly increase the complexed fraction of calcium. For example, massive transfusions of whole blood, in which citrate is used as an anticoagulant, can reduce the ionized $[Ca^{2+}]$ enough to produce tetany. In addition, because calcium and phosphate circulate at concentrations close to saturation, a substantial rise in the serum concentration of either calcium or phosphate can lead to the precipitation of calcium phosphate salts in tissues. This is a source of major clinical problems in patients with severe hypercalcemia (eg, malignant tumors) and in those with severe hyperphosphatemia (eg, in renal failure or rhabdomyolysis).

What is remarkable about calcium metabolism is that the serum-ionized $[Ca^{2+}]$, which represents a tiny fraction of the total body calcium, can be so tightly regulated in the face of the rapid fluxes of calcium through body compartments that take place during the course of calcium metabolism (Figure 8–1). The total calcium in extracellular fluid amounts to about 1% of total body calcium, with most of the remainder sequestered in bone. Yet from the extracellular fluid compartment, which contains about 900 mg of calcium, 10,000 mg/d is filtered at the glomerulus and 500 mg/d is added to a labile pool in bone; and to the extracellular fluid compartment are added about 200 mg absorbed from the diet, 9800 mg reabsorbed by the renal tubule, and 500 mg from bone.

The challenge of calcium homeostasis, then, is to maintain a constant level of ionized $[Ca^{2+}]$ in the extracellular fluid, simultaneously providing adequate amounts of calcium to cells, to bone, and for renal excretion—and all the while compensating, on an hourly basis, for changes in daily intake of calcium, bone metabolism, and renal function. It is scarcely surprising that this homeostatic task requires two hormones, PTH and $1,25(OH)_2D$, or that the secretion of each hormone is exquisitely sensitive to small changes in the serum calcium, or that each hormone is able to regulate calcium exchange across all three interfaces of the extracellular fluid: the gut, the bone, and the renal tubule. This chapter reexamines the integrated roles of PTH and $1,25(OH)_2D$ in calcium homeostasis after their actions and secretory control have been described.

The challenge of the cellular calcium economy is to maintain an intracellular $[Ca^{2+}]$ or $[Ca^{2+}]_i$ of ~100 nmol/L, about 10,000-fold less than what is present outside cells (~1.0 mmol/L), providing for rapid fluxes through the intracellular compartment, as required for regulation, while maintaining a large gradient across the cell membrane. The calcium gradient across the cell membrane is maintained by ATP-dependent calcium pumps, Na^+-Ca^{2+} exchangers, and the storage of calcium within intracellular sites. Calcium can enter cells through several types of Ca^{2+} channels, some of which are voltage-operated or receptor-operated, to provide for rapid influx in response to depolarization or receptor stimulation. The cell also maintains large stores of calcium in microsomal and mitochondrial pools and in some cells in the Golgi. Calcium can be released from microsomal stores rapidly by cellular signals such as 1,4,5-inositol trisphosphate (IP_3) (see Chapter 1). Reuptake mechanisms are also present, so that intracellular Ca^{2+} transients can be rapidly terminated by returning calcium to storage pools or pumping it across the plasma membrane.

PARATHYROID HORMONE

Anatomy and Embryology of the Parathyroid Glands

PTH is secreted from four glands located adjacent to the thyroid gland in the neck. The glands weigh an average of 40 mg each. The two superior glands are usually found near the posterior aspect of the thyroid capsule; the inferior glands are most often located near the inferior thyroid margin. However, the exact location of the glands is variable, and 12% to 15% of normal persons

FIGURE 8–1 Calcium fluxes in a normal individual in a state of zero external mineral balance. The blue arrows denote unidirectional calcium fluxes; the pink arrows denote net fluxes. (Reproduced with permission from Felig P, Baxter JD, Broadus AE, et al. *Endocrinology and Metabolism*. 2nd ed. New York: McGraw-Hill Education; 1987.)

have a fifth parathyroid gland. The parathyroid glands arise from the third and fourth branchial pouches. The inferior glands are actually those derived from the third branchial pouches. Beginning cephalad to the other pair, they migrate further caudad, and one of them sometimes follows the thymus gland into the superior mediastinum. The small size of the parathyroids and the vagaries of their location and number make parathyroid surgery a challenging procedure for all but the expert surgeon.

The parathyroid glands are composed of epithelial cells and stromal fat. The predominant epithelial cell is the **chief cell**. The chief cell is distinguished by its clear cytoplasm from the **oxyphil cell**, which is slightly larger and has eosinophilic granular cytoplasm. Both cell types contain PTH, and it is not known whether their secretory regulation differs in any fundamental way.

Secretion of Parathyroid Hormone

To regulate the extracellular calcium concentration ($[Ca^{2+}]_e$), PTH is under tight control by the serum $[Ca^{2+}]$. Thus, the negative feedback relationship of PTH with serum $[Ca^{2+}]$ is steeply sigmoidal, with the steep portion of the curve corresponding exactly to the normal range of serum $[Ca^{2+}]$—precisely the relationship to create a high "gain" controller and ensure maintenance of the normal serum ionized $[Ca^{2+}]$ by PTH (Figure 8–2).

To sense the serum ionized $[Ca^{2+}]$ and thereby regulate the secretion of PTH, the parathyroid cell relies on relatively high levels of expression of the extracellular calcium-sensing receptor (CaSR). CaSR is a 120-kDa G protein–coupled receptor belonging to family C of this superfamily (see Chapter 1). The CaSR has

sequence homologies to the metabotropic glutamate receptors of the central nervous system, the type B gamma-aminobutyric acid receptor, and a large family of pheromone receptors. The large extracellular domain of the CaSR mediates the sensing of calcium and other ions. Like other G protein–coupled receptors, the CaSR has seven membrane-spanning domains. The intracellular loops that connect these domains are directly involved in coupling the receptor to G proteins.

Mutations in this receptor are responsible for one form of familial hypocalciuric hypercalcemia (FHH), a disorder of calcium-sensing by the parathyroid glands and kidney. The CaSR is not unique to the parathyroid. CaSRs are widely distributed in the brain, skin, growth plate cartilage, bone, intestine, stomach, C cells, and other tissues. This receptor regulates the responses to calcium in thyroid C cells, which secrete calcitonin in response to high $[Ca^{2+}]_e$, and in the distal nephron of the kidney, where the receptor regulates both calcium excretion and water clearance among other important functions. The role of CaSRs in many other tissues is still unclear.

The primary intracellular signal by which an increased $[Ca^{2+}]_e$ inhibits the secretion of PTH appears to be an increase in $[Ca^{2+}]_i$. The CaSR is directly coupled through G_q to the enzyme phospholipase C, which hydrolyzes the phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2) to liberate the intracellular messengers IP_3 and diacylglycerol (see Chapter 1). IP_3 binds to a receptor in endoplasmic reticulum that releases calcium from membrane stores. The release of stored calcium raises the $[Ca^{2+}]_i$ rapidly and is followed by a sustained influx of extracellular calcium, through channels that produce a rise and sustained plateau in $[Ca^{2+}]_i$. Increased $[Ca^{2+}]_i$ may be sufficient for inhibition of PTH release, but it is unclear whether calcium release from intracellular stores or sustained calcium influx from the cell exterior is the more important source for calcium. The other product of phospholipase C action is the lipid diacylglycerol, an activator of the calcium- and phospholipid-sensitive protein kinases in the protein kinase C family. The effects of protein kinase C isoenzymes on the release of PTH from the gland are complex. CaSRs also couple to the inhibition of cyclic adenosine-3′,5′-monophosphate (cAMP) generation, which also may play a role in setting the response of parathyroid cells to ambient calcium levels, as well as other signaling pathways.

The initial effect of high $[Ca^{2+}]_e$ is to inhibit the secretion of preformed PTH from storage granules in the gland by blocking the fusion of storage granules with the cell membrane and release of their contents. In most cells, stimulation of exocytosis (*stimulus-secretion coupling*) is a calcium-requiring process, which is inhibited by depletion of extracellular calcium. The parathyroid cell is necessarily an exception to this rule, because this cell must increase secretion of PTH when the ionized $[Ca^{2+}]$ is low. In the parathyroids, intracellular magnesium may serve the role in stimulus-secretion coupling that calcium does in other cells. As discussed later in the section on hypoparathyroidism, depletion of magnesium stores can paralyze the secretion of PTH, leading to reversible hypoparathyroidism.

Besides calcium, there are several regulators of PTH secretion. Hypermagnesemia inhibits PTH, and during the treatment of
FIGURE 8–2 The relationship between the serum ionized $[Ca^{2+}]$ and the simultaneous serum concentration of intact PTH in normal humans. The serum calcium concentration was altered by the infusion of calcium (closed circles) or citrate (closed triangles). Parathyroid sensitivity to changes in serum calcium is maximal within the normal range (the shaded area). Low concentrations of PTH persist in the face of hypercalcemia. (Modified with permission from Conlin PR, et al. Hysteresis in the relationship between serum ionized calcium and intact parathyroid hormone during recovery from induced hyper- and hypocalcemia in normal humans. *J Clin Endocrinol Metab.* 1989 Sep;69(3):593-599.)

premature labor with infusions of magnesium sulfate, reductions in PTH levels and occasionally hypocalcemia are observed. Conversely, moderate hypomagnesemia can stimulate PTH secretion, even though prolonged depletion of magnesium will paralyze it. On a molar basis, magnesium is less potent in controlling secretion than calcium. Catecholamines, acting through β-adrenergic receptors and cAMP, stimulate the secretion of PTH. This effect does not appear to be clinically significant. The hypercalcemia sometimes observed in patients with pheochromocytoma usually has another basis—secretion of parathyroid hormone–related protein (PTHrP) by the tumor.

Not only do changes in serum ionized $[Ca^{2+}]$ regulate the secretion of PTH—they also regulate the synthesis of PTH at the level of stabilizing preproPTH mRNA levels. It is estimated that glandular stores of PTH are sufficient to maintain maximal rates of secretion for no more than 1.5 hours, so increased synthesis is required to meet sustained hypocalcemic challenges.

Transcription of the *PTH* gene is also regulated by vitamin D metabolites: high levels of 1,25(OH)₂D inhibit *PTH* gene transcription. This is one of many ways that the calciotropic hormones cooperatively regulate calcium homeostasis, and it has therapeutic implications. Vitamin D analogs are used to treat secondary hyperparathyroidism in dialysis patients.

Synthesis and Processing of Parathyroid Hormone

PTH is an 84-amino-acid peptide with a molecular weight of 9300. Its gene is located on chromosome 11. The gene encodes a precursor called preproPTH with a 29-amino-acid extension added at the amino terminus of the mature PTH peptide (Figure 8–3). This extension includes a 23-amino-acid signal sequence (the *pre* sequence) and a 6-residue prohormone sequence. The signal sequence in preproPTH functions precisely as it does in most other secreted protein molecules, to allow recognition of the peptide by a signal recognition particle, which binds to nascent peptide chains as they emerge from the ribosome and guides them to the endoplasmic reticulum, where they are inserted through the membrane into the lumen (Figure 8–4).

In the lumen of the endoplasmic reticulum, a signal peptidase cleaves the signal sequence from preproPTH to leave proPTH, which exits the endoplasmic reticulum and travels to the Golgi, where the *pro* sequence is cleaved from PTH by an enzyme called furin. Whereas preproPTH is evanescent, proPTH has a life span of about 15 minutes. The processing of proPTH is quite efficient, and proPTH, unlike other prohormones (eg, proinsulin), is not secreted. As it leaves the Golgi, PTH is repackaged into dense neuroendocrine-type secretory granules, where it is stored to await secretion.

FIGURE 8–3 Primary structure of human preproPTH hormone. The arrows indicate sites of specific cleavages which occur in the sequence of biosynthesis and peripheral metabolism of the hormone. The biologically active sequence is enclosed in the center of the molecule. (Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism*, 3rd ed. New York: McGraw-Hill Education; 1995.)

FIGURE 8–4   Biosynthetic events in the production of PTH within the parathyroid cell. *PreproPTH* gene is transcribed to its mRNA, which is translated on the ribosomes to preproPTH (amino acids –29 to +84). The presequence is removed within the endoplasmic reticulum, yielding proPTH (–6 to +84). Mature PTH (1-84) released from the Golgi is packaged in secretory granules and released into the circulation –in the presence of hypocalcemia. The CaSR, or CaR, senses changes in extracellular calcium that affect both the release of PTH and the transcription of the *preproPTH* gene. (Reproduced with permission from McPhee SJ and Lingappa VR. *Pathophysiology of Disease: An Introduction to Clinical Medicine.* New York: McGraw-Hill; 1995.)

Clearance and Metabolism of PTH

PTH secreted by the gland has a circulating half-life of 2 to 4 minutes. Intact PTH(1-84) is predominantly cleared in the liver and kidney. There, PTH is cleaved at the 33 to 34 and 36 to 37 positions to produce an amino terminal fragment and a carboxyl terminal fragment. Amino terminal fragments of PTH do not circulate to the same extent as carboxyl terminal fragments. The latter are cleared from blood by renal filtration, and they accumulate in chronic renal failure. Although the classic activities of PTH are encoded in the amino terminal portion of the molecule, mid region and carboxyl terminal fragments of the hormone may not be metabolically inert. These fragments may have their own receptors and biologic actions.

Assays of PTH

Current assays of intact PTH(1-84) employ two-site immunoradiometric assay (IRMA) or immunochemiluminescent assay (ICMA) techniques, in which the normal range for PTH is approximately 10 to 60 pg/mL (1-6 pmol/L). By utilizing antibodies to two determinants, one near the amino terminal end of the PTH molecule and the other near the carboxyl terminal end of PTH, these assays are designed to measure the intact, biologically active hormone species (Figure 8–5). In practice, such assays have sufficient sensitivity and specificity to detect not only increased levels of PTH in patients with hyperparathyroidism but also suppressed levels of PTH in patients with nonparathyroid hypercalcemia. The ability to detect suppression of PTH makes these assays powerful tools for the differential diagnosis of hypercalcemia. If hypercalcemia results from a form of hyperparathyroidism, then the serum PTH level will be high; if hypercalcemia has a *nonparathyroid* basis, then PTH will be suppressed.

Recently, intact PTH assays have been further refined so that the amino-terminal antibody recognizes only the most amino terminal residues of PTH (essentially amino acids 1-6). This improvement was made because it became clear that antibodies used in first-generation, two-site intact PTH assays were detecting species of PTH that were not PTH(1-84). There are
FIGURE 8–5 Schematic representation of the principle of the two-site assay for intact PTH. The label may be a luminescent probe or ^{125}I in the immunochemiluminescent or IRMA, respectively. Two different region-specific antibodies are used (Ab$_1$ and Ab$_2$). Only the hormone species containing both immunodeterminants is counted in the assay. Most recent whole or intact PTH immunoassays employ an Ab$_1$ directed against extreme *N*-terminal PTH epitopes as shown. (Reproduced with permission from McPhee SJ and Lingappa VR. *Pathophysiology of Disease: An Introduction to Clinical Medicine.* New York: McGraw-Hill; 1995.)

non-PTH(1-84) amino-terminally truncated PTH fragments generated *in vivo* by peripheral metabolism that can accumulate in patients with chronic renal failure [eg, PTH(7-84)]. About 50% of circulating PTH in patients with renal failure consists of large fragments of non-(1-84)PTH, and there is individual variation in these percentages. Assays specific for full-length PTH, in which the amino terminal antibodies truly detect residues at the extreme *N*-terminus of the molecule (residues 1-6), are designated as *whole, bioactive,* or *intact* PTH.

Biologic Effects of PTH

The central function of PTH is to regulate serum ionized [Ca^{2+}] levels by concerted effects on three principal target organs: bone, intestinal mucosa, and kidney. The effect of PTH on intestinal calcium absorption is indirect, resulting from increased production of the intestinally active vitamin D metabolite 1,25(OH)$_2$D. By its integrated effects on the kidney, gut, and bone, PTH acts to increase the inflow of calcium into the extracellular fluid and thus defend against hypocalcemia. Removal of the parathyroid glands results in profound hypocalcemia and ultimately in tetany and even death.

In the kidney, PTH has direct effects on the tubular reabsorption of calcium, phosphate, and bicarbonate. Although the bulk of calcium is resorbed from tubule fluid together with sodium in the proximal convoluted tubule, the fine-tuning of calcium excretion occurs in the distal nephron. There, PTH markedly increases the reabsorption of calcium, predominantly in the distal convoluted tubule. Although calcium is actively transported against an electrochemical gradient, the precise nature of the calcium transport process that is regulated by PTH is uncertain. However, from a physiologic standpoint, the ability to limit renal losses of calcium is one important means by which PTH defends the serum ionized [Ca^{2+}].

PTH inhibits the reabsorption of phosphate in the renal proximal tubule. In this nephron segment, phosphate is transported across the apical membrane of the tubule cell by specific sodium-phosphate cotransporters, with phosphate influx driven by the energy of the sodium gradient. PTH inhibits sodium-phosphate reabsorption by reducing the rate of insertion of transporters from a sequestered cytoplasmic pool into the apical membrane. The phosphaturic effect of PTH is profound. It is best quantified by calculating the tubular reabsorption of phosphate (TRP) from the clearances of phosphate and creatinine (TRP = $1 - C_p/C_{creat}$, normal range 80%-97%), or by calculating the renal phosphate threshold (TmP/GFR) from a standard nomogram. Because it is primarily the renal phosphate threshold that sets the level of serum phosphate, the phosphaturic effect of PTH is mirrored in the serum phosphorus level (eg, hypophosphatemia in hyperparathyroidism). Hyperparathyroid states may also be characterized by impaired bicarbonate reabsorption and a mild hyperchloremic metabolic acidosis, because of inhibition of Na$^+$-H$^+$ antiporter activity by PTH.

Although the hypocalciuric effect of PTH is readily understood as part of the concerted actions of the hormone to defend the serum ionized [Ca^{2+}], the utility of the phosphaturic effect of PTH is less obvious. One consideration is that the phosphaturic effect tends to prevent an increase in serum phosphate, which would otherwise result from the obligatory release of phosphate with calcium during bone resorption and would tend to dampen the homeostatic increase in serum ionized [Ca^{2+}] by complexing calcium in blood. An example is chronic kidney disease (CKD). When phosphate clearance is impaired by renal failure, the hypocalcemic effect of phosphate released during bone remodeling is an important contributor to progressive secondary hyperparathyroidism as part of a positive feedback loop—the more that bone resorption is stimulated and phosphate released, the more hyperparathyroidism is induced. Under those conditions, high serum levels of phosphate also stimulate PTH secretion.

Mechanism of Action of Parathyroid Hormone

There are two mammalian receptors for PTH. The first receptor to be identified recognizes PTH and PTHrP and is designated the PTH/PTHrP receptor, or the PTH-1 receptor (PTH-1R). The PTH-2R is activated by PTH only. These receptors also differ in their tissue distribution. The PTH-1R in kidney and bone is an 80,000-MW glycoprotein and member of the G protein receptor superfamily. It has the canonical architecture of such receptors,

with a large first extracellular domain, 7 membrane-spanning domains, and a cytoplasmic tail (see Chapter 1). PTH binds to sites in the large extracellular domain of the receptor. The hormone-bound form of the receptor then activates associated G proteins via several determinants in the intracellular loops. PTH receptors are closely related to a small subfamily of peptide hormone receptors, which includes those for secretin, vasoactive intestinal polypeptide (VIP), adrenocorticotropin hormone (ACTH), and calcitonin.

PTH itself has a close structural resemblance to a sister protein, PTHrP, and also resembles the peptides secretin, VIP, calcitonin, and ACTH. As noted earlier, the receptors for these related ligands are themselves members of a receptor subfamily. These peptide hormones have an amino terminal alpha helical domain, thought to be directly involved in receptor activation, and an adjacent alpha helical domain that seems to be the primary receptor-binding domain. In the case of PTH, residues 1 to 6 are required for activation of the receptor; truncated analogs without these residues [eg, PTH(7-34)] can bind the receptor but cannot efficiently activate it and thus serve as competitive antagonists of PTH action. The primary receptor-binding domain consists of PTH(18-34). Although the intact form of PTH is an 84-amino-acid peptide, PTH(35-84) does not seem to have any important role in binding to the bone-kidney receptor. However, a separate PTH(35-84) receptor may exist; the carboxyl terminal PTH receptor could mediate an entirely different set of actions of PTH.

The PTH-1 receptor binds PTH and PTHrP with equal affinity. Physiologic activation of the receptor by binding of either PTH or PTHrP induces the active, GTP-bound state of two receptor-associated G proteins. G_s couples the receptor to the effector adenylyl cyclase and thereby to the generation of cAMP as a cellular second-messenger. G_q couples the receptor to a separate effector system, phospholipase C, and thereby to an increase in $[Ca^{2+}]_i$ and to activation of protein kinase C (see Chapter 1). Although it is not clear which of the cellular messengers, cAMP, $[Ca^{2+}]_i$, or diacylglycerol is responsible for each of the various cellular effects of PTH, there is evidence from an experiment of nature that cAMP is the key second-messenger for maintaining calcium homeostasis and renal phosphate excretion. The experiment is pseudohypoparathyroidism (PHP), in which null mutations in one allele of the stimulatory G protein subunit G_s alpha (GNAS) cause hypocalcemia and unresponsiveness of renal phosphate excretion to PTH.

PTHrP

When secreted in abundance by malignant tumors, PTHrP produces severe hypercalcemia by activating the PTH-1 receptor. However, the physiologic roles of PTHrP are quite different from those of PTH. PTHrP is produced in many fetal and adult tissues. Based on gene knockout experiments and overexpression of PTHrP in individual tissues, we now know that PTHrP is required for normal development as a regulator of the proliferation and mineralization of chondrocytes and as a regulator of placental calcium transport. In postnatal life, PTHrP also appears to regulate epithelial-mesenchymal interactions that are critical for development of the mammary gland, skin, and hair follicle. In most physiologic circumstances, PTHrP carries out local rather than systemic actions. PTHrP is discussed fully in Chapter 21.

Calcitonin

Calcitonin (CT) is a 32-amino-acid peptide whose principal function is to inhibit osteoclast-mediated bone resorption. CT is secreted by parafollicular C cells of the thyroid. These are neuroendocrine cells derived from the ultimobranchial body, which fuses with the posterior lobes of the thyroid to become the C cell mass (about 0.1% of the thyroid gland).

The secretion of CT is under the control of the ionized $[Ca^{2+}]$. The C cell uses the same CaSR as the parathyroid cell to sense changes in the ambient ionized $[Ca^{2+}]$. In contrast to parathyroid cells, C cells increase secretion of CT in response to hypercalcemia and shut off hormone secretion during hypocalcemia.

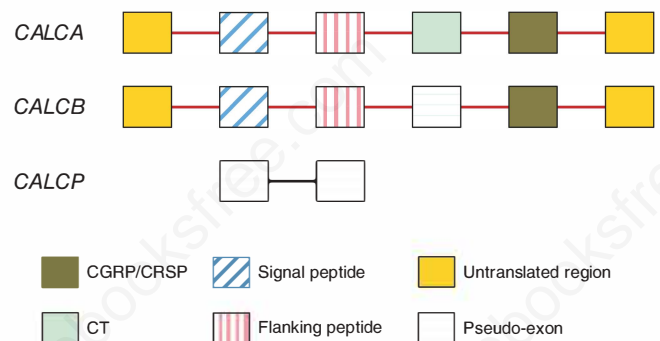
CT is a member of the CT gene–related peptide (CGRP) superfamily that includes: CT, CGRP, CT-receptor–stimulating peptide (CRSP), adrenomedullin, and amylin. CT and CGRP are encoded by one gene, and the respective peptides are generated from alternative splicing of primary RNA transcripts in a tissue-selective manner, with CT made predominantly in the thyroid C cells. The genomic structure of the *CT/CGRP/CRSP* gene family is shown in Figure 8–6. In humans, there are two genes (*CALCA* and *CALCB*) that encode CGRPs and CT and one pseudogene (*CALCP*). Transcription of CALCA produces CT and CGRP in a tissue-specific manner by alternative splicing. The *CALCB* gene has a coding CGRP-beta exon and an exon that encodes for CT, but in which there is an in-frame stop codon. Thus, CALCB generates only CGRP-beta. In the thyroid C cell, mature CT (Figure 8–7) is incorporated within a


FIGURE 8–6 Genomic structure of the human calcitonin (CT)/ calcitonin gene–related peptide (CGRP)/CT-receptor–stimulating peptide (CRSP) family of genes which includes CALCA and CALCB and the pseudogene CALCP. Alternative splicing generates the two gene products (CT in the thyroid C cells and CGRP in the nervous system) with well-defined functions in humans. Straight lines indicate the introns while the coding sequences are shown by specifically designated boxes. (Data from Katafuchi T, Yasue H, Osaki T, et al. Calcitonin receptor-stimulating peptide: its evolutionary and functional relationship with calcitonin/calcitonin gene-related peptide based on gene structure. *Peptides.* 2009 Sep;30(9):1753-1762.)

141-amino-acid precursor. In neurons of the central nervous system, CGRP is produced from a 128-amino-acid precursor. CGRP is a 37-amino-acid peptide with considerable homology to CT. The amino termini of both peptides incorporate a 7-member disulfide-bonded ring (see Figure 8–7). Acting through its own receptor, CGRP is among the most potent vasodilator substances known. When administered intravenously, CT produces a rapid and dramatic decline in levels of serum calcium and phosphate, primarily through actions on bone. The major effect of the hormone is to inhibit osteoclastic bone resorption. After exposure to CT, the morphology of the osteoclast changes rapidly. Within minutes, the cell withdraws its processes, shrinks in size, and retracts the ruffled border, the organelle of bone resorption, from the bone surface. Osteoclasts and cells of the proximal renal tubule express CT receptors. Like the PTH receptor, this is a receptor coupled through G_s alpha to adenylyl cyclase and thereby to the generation of cAMP in target cells. CT also has mild renal effects. In the kidney, CT inhibits the reabsorption of phosphate, thus promoting renal phosphate excretion. CT also induces a mild natriuresis and increases the renal excretion of calcium. The renal effects of CT are not essential for its acute effect on serum calcium levels, which results from blockade of bone resorption.

Although its secretory control by calcium and its antiresorptive actions enable CT to counter PTH in the control of calcium homeostasis, thus engendering bihormonal regulation, it is actually unlikely that CT plays an essential physiologic role in humans and other terrestrial animals. This is supported by two lines of evidence. First, removal of the thyroid gland—the major if not the only source of CT in mammals—has no perceptible impact on calcium handling or bone metabolism in postnatal life. Second, secretion of extremely high CT levels by medullary carcinoma of the thyroid (MCT), a malignancy of the C cell, likewise has no apparent effect on mineral homeostasis. Thus, in humans, CT is a hormone in search of an essential function. It plays a much more obvious homeostatic role in saltwater fish, in which the major challenge is maintenance of blood calcium levels in the sea, where the ambient calcium concentration of seawater is very high.

CT is of clinical interest for two reasons. First, serum CT is important as a tumor marker in MCT. Second, CT has

therapeutic uses as an inhibitor of osteoclastic bone resorption. CT can be administered either parenterally or as a nasal spray and is used in the treatment of Paget disease of bone, hypercalcemia, and osteoporosis.

VITAMIN D

Nomenclature

The term vitamin D (calciferol) refers to two secosteroids: vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol) (Figure 8–8). Both are produced by photolysis from naturally occurring sterol precursors. Vitamin D_2 had been the principal form of vitamin D available for pharmaceutical purposes other than as dietary supplements, although this is changing as formulations with high doses of vitamin D_3 (eg, 10,000-50,000 units) are becoming more widely available (Table 8–2). Vitamin D_3 is produced from 7-dehydrocholesterol, a precursor of cholesterol found in high concentration in the skin. Although vitamin D_2 is metabolized somewhat differently than vitamin D_3, the active metabolites of vitamin D_2 and vitamin D_3 have equivalent biologic activity so the term "vitamin D," unless otherwise qualified, will be understood here to denote both. Vitamins D_2 and D_3 differ in their side chains: vitamin D_2 has a methyl group at C24 and a double bond at C22 to C23. These features alter the metabolism of vitamin D_2 compared with vitamin D_3; however, both are converted to 25-hydroxyvitamin D [25(OH)D] and 1,25-dihydroxyvitamin D [1,25(OH)$_2$D].

In the process of forming vitamins D_2 and D_3, the B ring of the sterol precursor is cleaved, and the A ring is rotated around the C5 to C6 double bond so that the 3β-hydroxyl group is positioned below the plane of the A ring. By convention, this hydroxyl group retains its designation as 3β, and the one position above the plane of the A ring is designated 1α. Hydroxylations in the side chain can lead to stereoisomers designated R and S. The natural position for the C24 hydroxyl group is R. Both the R and the S positions can be hydroxylated at C25 in the formation of 25,26(OH)$_2$D.

Because vitamin D can be formed *in vivo* (in the epidermis) in the presence of adequate amounts of ultraviolet light, it is more
FIGURE 8–8 The photolysis of ergosterol and 7-dehydrocholesterol to vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol), respectively. An intermediate is formed after photolysis (preD), which undergoes a thermal-activated isomerization to the final form of vitamin D. The rotation of the A-ring puts the 3-beta-hydroxyl group into a different orientation with respect to the plane of the A-ring during production of vitamin D.

properly considered a hormone (or prohormone) than a vitamin. To be biologically active, vitamin D must be metabolized further. The liver is the major but not the only organ that can metabolize vitamin D to its principal circulating form, 25(OH)D. The kidney and other tissues metabolize 25(OH)D to a variety of other metabolites, the most important of which are $1,25(OH)_2D$ and perhaps $24,25(OH)_2D$. A large number of other metabolites have been identified, but their physiologic roles are unclear. They may represent products destined only for elimination. Normal circulating levels of the principal metabolites are listed in Table 8–3. The recommended daily allowance for vitamin D in adults by the Institute of Medicine is 600 to 800 units (1 unit = 0.025 µg vitamin D), although the guidelines from the Endocrine Society recommend higher doses (eg, 2000 units) especially in older individuals who tend to have vitamin D deficiency or insufficiency more commonly.

TABLE 8–2 Commonly used vitamin D metabolites and analogs.

	Cholecalciferol, Ergocalciferol	Paricalcitol	Doxercalciferol	Calcitriol
Abbreviation	D_3, D_2	19-nor calcitriol	$1\alpha OHD_2$	$1,25(OH)_2D$

TABLE 8–3 Vitamin D and its metabolites.

Name	Abbreviation	Generic Name	Serum Concentration[a]
Vitamin D	D	Calciferol	1.6 ± 0.4 ng/mL
Vitamin D_3	D_3	Cholecalciferol	
Vitamin D_2	D_2	Ergocalciferol	
25-Hydroxyvitamin D	25(OH)D	Calcifediol	26.5 ± 5.3 ng/mL
1,25-Dihydroxyvitamin D	$1,25(OH)_2D$	Calcitriol	34.1 ± 0.4 pg/mL
24,25-Dihydroxyvitamin D	$24,25(OH)_2D$		1.3 ± 0.4 ng/mL
25,26-Dihydroxyvitamin D	$25,26(OH)_2D$		0.5 ± 0.1 ng/mL

[a]Values differ somewhat from laboratory to laboratory depending on the methodology used, sunlight exposure, and dietary intake of vitamin D in the population study. Children tend to have higher $1,25(OH)_2D$ levels than do adults.

Data from Bikle D. *Assay of Calcium Regulating Hormones*. New York: Springer; 1983.

Cutaneous Synthesis of Vitamin D

Vitamin D_3 is formed in the skin from 7-dehydrocholesterol, which is distributed throughout the epidermis and dermis but has its highest concentration in the lower layers of the epidermis, the stratum spinosum, and stratum basale. These epidermal layers also account for the highest production of vitamin D. The cleavage of the B ring of 7-dehydrocholesterol to form previtamin D_3 (see Figure 8–8) requires ultraviolet light with a spectrum of 280 to 320 nm (UVB). Following cleavage of the B ring, the previtamin D_3 undergoes thermal isomerization to vitamin D_3 but also to the biologically inactive compounds lumisterol and tachysterol. Formation of pre-D_3 is rapid and reaches a maximum within hours during exposure to solar or ultraviolet irradiation. The degree of epidermal pigmentation, the age of the skin, and the intensity of exposure all affect the time required to reach the maximum pre-D_3 concentration but do not alter that maximum. Continued ultraviolet light exposure then results in continued formation of the inactive compounds from pre-D_3. The formation of lumisterol is reversible, so lumisterol can be converted back to pre-D_3 as pre-D_3 levels fall. Short exposure to sunlight causes prolonged release of vitamin D_3 from the exposed skin because of the slow conversion of pre-D_3 to vitamin D_3 and the conversion of lumisterol to pre-D_3. Prolonged exposure to sunlight does not produce toxic quantities of vitamin D_3 because of the photoconversion of pre-D_3 to lumisterol and tachysterol.

Vitamin D_3 transport from the skin into the circulation has not been thoroughly studied. Vitamin D_3 is carried in the bloodstream primarily bound to vitamin D–binding protein (DBP), an α-globulin produced in the liver. DBP has a lower affinity for vitamin D_3 than other vitamin D metabolites such as 25(OH)D and $24,25(OH)_2D$. 7-Dehydrocholesterol, pre-D_3, lumisterol, and tachysterol bind to DBP even less well. Therefore, vitamin D_3 could be selectively removed from skin by the gradient established by selective binding to DBP. Because the deepest levels of the epidermis make the most vitamin D_3 when the skin is irradiated, the distance over which vitamin D_3 must diffuse to reach the circulation is short. However, simple diffusion is an unlikely means for so hydrophobic a molecule to enter the bloodstream. Epidermal lipoproteins may play a role in transport, but this remains to be established.

Dietary Sources and Intestinal Absorption

Dietary sources of vitamin D are clinically important because exposure to ultraviolet light may not be sufficient to maintain adequate production of vitamin D in the skin. The farther away from the equator one lives, the shorter the period of the year during which the intensity of sunlight is sufficient to produce vitamin D_3. Most milk products in the United States are supplemented with vitamin D. Unfortified milk products contain little or no vitamin D. Although plants and mushrooms contain ergosterol, their content of vitamin D_2 is limited unless they are irradiated with ultraviolet light during processing. Vitamin D is found in moderate to high concentrations in fish oils and fish liver and in lesser concentrations in eggs. Vitamin D is absorbed from the diet in the small intestine with the help of bile salts. Drugs that bind bile salts such as colestipol and various malabsorption syndromes reduce vitamin D absorption. Most of the vitamin D passes into the lymph in chylomicrons, but a significant amount is absorbed directly into the portal system. The presence of fat in the lumen decreases vitamin D absorption. 25(OH)D and calcitriol are preferentially absorbed into the portal system and are less influenced by the amount of fat in the lumen. Biliary conjugates of the vitamin D metabolites have been identified, and an enterohepatic circulation of these metabolites has been established. Vitamin D is taken up rapidly by the liver and is metabolized to 25(OH)D. 25(OH)D is also transported in the blood bound to DBP. Little vitamin D is stored in the liver. Excess vitamin D is stored in adipose tissue and muscle.

Binding Proteins for Vitamin D Metabolites

As noted earlier, vitamin D metabolites are transported in the blood bound principally to DBP (85%) and albumin (15%). DBP binds 25(OH)D and $24,25(OH)_2D$ with approximately 30 times greater affinity than it binds $1,25(OH)_2D$ and vitamin D. In most species including humans, DBP binds the D_3 metabolites with greater affinity than the D_2 metabolites, which alter their pharmacokinetics. DBP circulates at a concentration (5×10^{-6} mol/L) approximately 50 times greater than the total concentrations of the vitamin D metabolites. DBP levels are reduced in

liver disease and in the nephrotic syndrome and increased during pregnancy and with estrogen administration, but are not altered by states of vitamin D deficiency or excess. The high affinity of DBP for the vitamin D metabolites and the large excess-binding capacity maintain the free and presumed biologically active concentrations of the vitamin D metabolites at very low levels—approximately 0.03% and 0.4% of the total 25(OH)D and 1,25(OH)$_2$D levels, respectively. Liver disease reduces the total level of the vitamin D metabolites commensurate with the reduction in DBP and albumin levels, but the free concentrations of the vitamin D metabolites remain normal in most subjects. This fact must be borne in mind when evaluating a patient with liver disease to determine whether such a patient is truly vitamin D deficient. Pregnancy, on the other hand, increases both the free and total concentrations by increasing DBP levels, altering the binding of the metabolites to DBP, and increasing the production of 1,25(OH)$_2$D. The binding of the vitamin D metabolites to DBP appears to occur at the same site, and saturation of this site by one metabolite can displace the other metabolites. This is an important consideration in vitamin D toxicity because the very high levels of 25(OH)D that characterize this condition displace the often normal levels of 1,25(OH)$_2$D, leading to elevated free and biologically active concentrations of 1,25(OH)$_2$D. This phenomenon at least partially explains the hypercalcemia and hypercalciuria that mark vitamin D intoxication even in patients with normal total 1,25(OH)$_2$D levels.

At present, it is not clear whether DBP functions just to maintain a circulating reservoir of vitamin D metabolites or whether DBP participates in transporting the vitamin D metabolites to their target tissues. However, some tissues, such as the kidney and parathyroid gland, express megalin and cubilin that enable DBP-bound metabolites to be transported into cells. A different set of proteins, related to heat shock proteins, are found within cells that bind the vitamin D metabolites and appear to facilitate their further metabolism. These proteins are distinct from DBP and the nuclear hormone receptors for calcitriol, which will be discussed subsequently.

Metabolism

The conversion of vitamin D to 25(OH)D occurs principally in the liver (Figure 8–9). Both mitochondria and microsomes have the capacity to produce 25(OH)D but with different kinetics and with different enzymes. The mitochondrial enzyme has been identified as the 5-β–cholestane-3α,7α,12α-triol-27(26)-hydroxylase (CYP27A1), a cytochrome P450 mixed-function oxidase, and its cDNA has been isolated. A number of microsomal P450 enzymes have been shown to have 25-hydroxylase activity with variable preference for D$_2$ or D$_3$ and their 1-hydroxylated metabolites. The microsomal 25-hydroxylase that has received the most attention is CYP2R1. Like the mitochondrial enzyme, these are not specific for vitamin D. Regulation of 25(OH)D
FIGURE 8–9 The metabolism of vitamin D. The liver converts vitamin D to 25(OH)D. The kidney converts 25(OH)D to 1,25(OH)$_2$D and 24,25(OH)$_2$D. Control of metabolism is exerted primarily at the level of the kidney where low serum phosphate, low serum calcium, and high parathyroid hormone (PTH) levels favor production of 1,25(OH)$_2$D whereas FGF23, high serum calcium and phosphate, and 1,25(OH)$_2$D inhibit 1,25(OH)$_2$D production while increasing 24,25(OH)$_2$D production. Plus (+) and minus (−) signs denote the stimulatory and inhibitory enzymatic reactions, respectively, driving the metabolic steps indicated.

production is difficult to demonstrate. Drugs such as phenytoin and phenobarbital reduce serum 25(OH)D levels, primarily by increased catabolism of 25(OH)D and vitamin D. Liver disease leads to reduced total (but not necessarily free) serum 25(OH)D levels, primarily because of reduced DBP and albumin synthesis and not reduced synthesis of 25(OH)D. Vitamin D deficiency is marked by low blood levels of 25(OH)D, primarily because of lack of substrate for the 25-hydroxylase. Vitamin D intoxication, on the other hand, leads to increased levels of 25(OH)D because of the lack of feedback inhibition on the 25-hydroxylases.

Control of vitamin D metabolism is exerted principally in the kidney (see Figure 8–9). $1,25(OH)_2D$ and $24,25(OH)_2D$ are produced by cytochrome mixed-function oxidases in mitochondria of the proximal tubules. cDNAs encoding these enzymes have both been identified and show substantial homology to each other and to the mitochondrial 25-hydroxylase (CYP27A1). Their homology to other mitochondrial steroid hydroxylases

is considerable but not as high. Both 24-hydroxylase and 1-hydroxylase are widely distributed. Their roles in extra-renal tissues appear to be paracrine or autocrine, with limited contribution to circulating levels of their metabolic products.

The kidney remains the principal source of circulating $1,25(OH)_2D$. Production of $1,25(OH)_2D$ in the kidney is stimulated by PTH and insulin-like growth factor-1 (IGF-1) and is inhibited by fibroblast-derived growth factor 23 (FGF23) and high blood levels of calcium and phosphate. Production of FGF23, a recently identified hormone, occurs primarily in bone and is regulated by the levels of serum phosphate and $1,25(OH)_2D$ (Figure 8–10). FGF23 inhibits $1,25(OH)_2D$ production, blocks renal phosphate reabsorption, and acts to lower serum phosphate (see Figure 8–10 and Chapter 21).

Calcium and phosphate also have both direct and indirect effects on $1,25(OH)_2D$ production. In addition to direct actions on the 1-hydroxylase to reduce its activity, calcium inhibits PTH
FIGURE 8–10 A simplified schema for the regulation of serum phosphate by PTH, $1,25(OH)_2D$ and fibroblast growth factor 23 (FGF23). FGF23 is produced predominantly by osteocytes buried deep in the bone matrix. Its actions are mediated by FGF receptors, differing in their expression in different tissues, and by the membrane co-receptor molecule alpha klotho. The alpha klotho/FGF receptor complex mediates high-affinity activation of signal transduction by FGF23 in key target tissues. FGF23 has potent effects on calcium and phosphate homeostasis as shown. FGF23 reduces $1,25(OH)_2D$ production by reducing 1-alpha hydroxylase activity and expression and increases its catabolism by enhancing 24-hydroxylase activity and expression. Together this reduces levels of $1,25(OH)_2D$, which has downstream effects to reduce intestinal calcium and phosphate absorption. FGF23 also reduces the expression of key phosphate transporters in the kidney (NaPi2a and NaPi2c) thereby facilitating the excretion of phosphate. The reciprocal interaction between PTH and FGF23 is unclear and may depend on the physiologic circumstances, but PTH independently also stimulates phosphate excretion via the same NaPi transporters. The combined actions of FGF23 lower serum phosphate concentrations. Not displayed here are the negative feedback control mechanisms including: the ability of $1,25(OH)_2D$ and phosphate to stimulate FGF23 production in bone and the suppression of PTH secretion by $1,25(OH)_2D$. Excessive FGF23 production and/or action (hypophosphatemia, chronic phosphate wasting) can result in abnormal bone matrix mineralization, causing rickets or osteomalacia.

secretion by the parathyroid glands, and this lowers renal $1,25(OH)_2D$ production. Phosphate inhibits the production of growth hormone by the pituitary gland, leading to decreased IGF-1 generation, and stimulates FGF23 production, each step contributing to the indirect inhibition of $1,25(OH)_2D$ production by phosphate.

$1,25(OH)_2D$ inhibits its own synthesis at least in the kidney (but not in other tissues) and stimulates the production of $24,25(OH)_2D$ and $1,24,25(OH)_3D$ by the 24-hydroxylase, which are the initial products of both $25(OH)D$ and $1,25(OH)_2D$ catabolism, respectively. Other hormones such as prolactin and CT may regulate $1,25(OH)_2D$ production, but their roles under normal physiologic conditions in humans have not been demonstrated.

Extrarenal production of $1,25(OH)_2D$ is regulated in a cell-specific fashion. Cytokines such as γ-interferon (γ-IFN) and tumor necrosis factor-α (TNF-α) stimulate $1,25(OH)_2D$ production by macrophages and keratinocytes. $1,25(OH)_2D$ and calcium have minimal effects on $1,25(OH)_2D$ production by these cells. This is important in understanding the pathophysiology of hypercalcemia and the increased $1,25(OH)_2D$ levels in patients with sarcoidosis, lymphomas, and other granulomatous diseases, in that feedback regulation by calcium and $1,25(OH)_2D$ does not occur.

Mechanisms of Action

The main function of vitamin D metabolites is the regulation of calcium and phosphate homeostasis, which occurs in conjunction with PTH. The gut, kidney, and bone are the principal target tissues for this regulation. The major pathologic complication of vitamin D deficiency is rickets (in children with open epiphyses) or osteomalacia (in adults), which results mainly from the deficiency of calcium and phosphate required for bone mineralization. $1,25(OH)_2D$ is the most biologically active, if not the only vitamin D metabolite involved in maintaining calcium and phosphate homeostasis.

Most of the cellular processes regulated by $1,25(OH)_2D$ involve the nuclear vitamin D receptor (VDR), a 50-kDa protein related by structural and functional homology to a large class of nuclear hormone receptors including the steroid hormone receptors, thyroid hormone receptors (TRs), retinoic acid and retinoid X receptors (RARs, RXRs), and endogenous metabolite receptors, including peroxisome proliferation activator receptors (PPARs), liver X receptors (LXRs), and farnesoid X receptors (FXRs) (see Chapter 1). These receptors are transcription factors. VDRs, as is the case with TRs, RARs, PPARs, LXRs, and FXRs, generally act by forming heterodimers with RXRs. The VDR–RXR complex then binds to specific regions within the regulatory portions of the genes whose expression is controlled by $1,25(OH)_2D$ (Figure 8–11). The regulatory regions are called vitamin D response elements (VDREs) and are generally composed of two stretches of six nucleotides (each called a half-site) with a specific and nearly identical sequence separated by three nucleotides with a less specific sequence (a direct repeat with three base-pair separation; DR3). Numerous exceptions to this rule can be found such as a
FIGURE 8–11 $1,25(OH)_2D$-initiated gene transcription. $1,25(OH)_2D$ enters the target cell and binds to its receptor, VDR. The VDR then heterodimerizes with the retinoid X receptor, RXR. This increases the affinity of the VDR–RXR complex for the VDRE, a specific sequence of nucleotides in the promoter region of a vitamin D responsive gene. Binding of the VDR–RXR complex to the VDRE attracts a complex of proteins termed coactivators to the VDR–RXR complex, some of which open up the gene for transcription by acetylating the histones and other proteins which communicate with and activate the RNA polymerase II complex. Transcription of the gene is initiated to produce the corresponding mRNA, which leaves the nucleus for the cytoplasm to be translated to the corresponding protein.

VDR–RAR complex binding to a DR6 (direct repeat with six base-pair separation) or inverted palindromes (repeat elements going in opposite directions) with various degrees of spacing (eg, IP9). Other nuclear hormone receptors bind to similar elements but with different spacing or orientation of the half-sites. The binding of the VDR–RXR complex to the VDRE then attracts a number of other proteins called coactivators, which may function to open up the gene for transcription by acetylating the histones covering the gene or by bridging the gap between the VDRE and the initiation complex containing the RNA polymerase to signal the beginning of transcription. Not all actions of $1,25(OH)_2D$, however, can be explained by changes in gene expression. VDRs in the membrane and a membrane-bound protein identified as protein disulfide isomerase A3 (Pdia3), initially known as the $1,25D_3$-membrane–associated rapid response steroid binding protein ($1,25D_3$-MARRS), may mediate the rapid effects of $1,25(OH)_2D$ on calcium influx and protein kinase C activity observed in a number of tissues, effects too rapid to be explained by genomic activity.

A. Intestinal calcium and phosphate transport   Intestinal calcium transport is the best understood target tissue response of $1,25(OH)_2D$. Calcium transport through the intestinal epithelium proceeds by at least three distinct steps: (1) entrance into the cell from the lumen across the brush border membrane down a steep electrochemical gradient; (2) passage through the cytosol, probably within subcellular organelles such as mitochondria and endosomes; and (3) removal from the cell against a steep electrochemical gradient at the basolateral membrane.

Each of these steps is regulated by 1,25(OH)$_2$D. At the brush border, 1,25(OH)$_2$D induces a change in the binding of calmodulin to brush border myosin 1, a unique form of myosin found only in the intestine, where it resides primarily in the microvillus bound to actin and to the plasma membrane. The calmodulin-myosin 1 complex may provide the mechanism for removing calcium from the brush border after it crosses the membrane into the cell. Changes in the phospholipid composition of the brush border may explain the increased flux of calcium across this membrane after calcitriol administration. None of these changes requires new protein synthesis. On the other hand, a Ca^{2+} channel, the transient receptor potential cation channel 6 (TRPV6) in the brush border membrane, is induced by 1,25(OH)$_2$D and is likely the major mechanism by which calcium enters the intestinal epithelial cell. The transport of calcium through the cytosol requires a vitamin D-inducible protein called calbindin. Calbindin exists either in a 28-kDa or 9-kDa form, depending on the species and tissue. Calbindin has a high affinity for calcium. If its synthesis is blocked, the calcium content of the cytosol and mitochondria increases, and efficiency of transport is reduced. At the basolateral membrane, calcium is removed from the cell by an ATP-driven pump, the Ca^{2+}-ATPase (PMCA1b), a protein also induced by 1,25(OH)$_2$D. Recent studies, however, in which calbindin or TRPV6 expression is deleted show surprisingly little impact on intestinal calcium transport (calbindin knockout) or only a partial reduction (TRPV6 knockout) suggesting that there is more to learn about the mechanisms governing intestinal calcium transport. Nevertheless in mice in which the VDR is rendered nonfunctional (VDR knockout), intestinal calcium transport is markedly impaired, indicating the importance of VDR function—presumably via regulation of gene expression—in governing intestinal calcium transport.

The regulation of phosphate absorption from the intestine is less well understood. It occurs primarily in the jejunum. The sodium phosphate transporter, NaPiIIb, a member of the family of phosphate transporters that includes NaPiIIa and IIc in the kidney, is thought to be the main mechanism by which phosphate is absorbed from the luminal contents of the intestine. 1,25(OH)$_2$D increases the levels of NaPiIIb in the apical (luminal) membrane, but a direct stimulation of NaPiIIb expression has not been clearly shown. Moreover, in states of dietary phosphate restriction, phosphate absorption is increased even in animals lacking either the VDR or Cyp27b1, indicating that vitamin D independent factors also control phosphate absorption.

B. Actions of vitamin D in bone   The critical role of 1,25(OH)$_2$D in regulating bone formation and resorption is evidenced by the development of rickets in children who are vitamin D-deficient, have inactivating mutations in *CYP27B1* (the 1-hydroxylase) (pseudovitamin D-deficiency rickets), or lack a functioning VDR [hereditary 1,25(OH)$_2$D-resistant rickets]. The histologic and radiologic appearance of bone in these genetic conditions is quite similar to that in patients with severe vitamin D deficiency.

Patients with inactivating mutations in the *1-hydroxylase* can be treated successfully with calcitriol (but not with vitamin D), whereas those with mutations in *VDR* are resistant to calcitriol as well as to vitamin D. These experiments of nature, however, do not exclude the possibility that other vitamin D metabolites, in combination with 1,25(OH)$_2$D, are essential for normal bone metabolism.

In vitamin D deficiency, all vitamin D metabolites are reduced, but 25(OH)D and 24,25(OH)$_2$D tend to be reduced out of proportion to 1,25(OH)$_2$D, which may be maintained in the low normal range despite clear abnormalities in bone mineralization. Thus, it is reasonable to ask whether 1,25(OH)$_2$D is the only vitamin D metabolite of consequence for the regulation of skeletal homeostasis. In fact, a number of studies point to unique actions of 24,25(OH)$_2$D that cannot be replicated by 1,25(OH)$_2$D, especially in cartilage, although this remains controversial. Studies in mice, in which the *24-hydroxylase* has been inactivated (knocked-out), support the concept that 24,25(OH)$_2$D has a role in bone formation that is not replaced by 1,25(OH)$_2$D. Despite those observations, many of the metabolic and skeletal abnormalities in 24-hydroxylase–null animals (including humans) may be explained by their inability to regulate 1,25(OH)$_2$D levels. Nevertheless, the need for more than just 1,25(OH)$_2$D is an important concept in the treatment of vitamin D deficiency; this is best done with vitamin D or 25(OH)D rather than calcitriol alone, because vitamin D serves as a precursor for both 1,25(OH)$_2$D and 24,25(OH)$_2$D.

The mechanisms by which 1,25(OH)$_2$D regulates skeletal homeostasis remain uncertain. Provision of adequate calcium and phosphate for mineralization is clearly important. The rickets present in patients with defective VDRs can be cured with calcium infusions. Similarly, in mice in which the VDR is rendered nonfunctional (knocked-out), rickets is prevented with diets high in calcium and phosphate. Thus, even though the osteoblast, the cell responsible for forming new bone, expresses VDR, and the transcription of a number of proteins in bone is regulated by 1,25(OH)$_2$D, it is not clear how essential the direct actions of 1,25(OH)$_2$D on bone are for bone formation and mineralization. Thus, bone is a good example of a tissue in which 1,25(OH)$_2$D and calcium work together, such that limited quantities of one may be compensated for by increased amounts of the other. However, recent studies suggest that although 1,25(OH)$_2$D promotes bone formation in situations of adequate calcium, it inhibits bone formation when the 1,25(OH)$_2$D levels are high, but calcium levels are low.

In organ cultures of bone, the best established action of 1,25(OH)$_2$D is to stimulate bone resorption. This is accompanied by an increase in osteoclast number and activity and decreased collagen synthesis. The increase in osteoclast number and activity is now known to be mediated by the production in osteoblasts of a membrane-bound protein called receptor activator of NF-kappa B ligand (RANKL), which acts on its receptor (RANK) in osteoclasts and their precursors to stimulate osteoclast differentiation and activity (discussed later). 1,25(OH)$_2$D is one of several hormones (PTH and selected cytokines are others) that stimulate RANKL production. Vitamin D deficiency does not decrease

bone resorption, probably because PTH levels are elevated. High levels of PTH could, therefore, compensate for the lack of $1,25(OH)_2D$ at the level of RANKL production. The presence of partial skeletal resistance to PTH in patients with vitamin D deficiency may be explained by this mechanism.

$1,25(OH)_2D$ also promotes the differentiation of osteoblasts. This action is less well-delineated than the promotion of osteoclast differentiation. Osteoblasts pass through a well-defined sequence of biochemical processes as they differentiate from proliferating osteoprogenitor cells to cells capable of producing and mineralizing matrix. The effect of $1,25(OH)_2D$ on the osteoblast depends on the stage of differentiation at which the $1,25(OH)_2D$ is administered. Early in the differentiation process, in cells characterized as immature osteoblast-like cells, $1,25(OH)_2D$ stimulates collagen production and alkaline phosphatase activity. These functions are inhibited in more mature osteoblasts. On the other hand, osteocalcin production is stimulated by $1,25(OH)_2D$ only in mature osteoblasts. Experiments *in vivo* demonstrating that excessive $1,25(OH)_2D$ can inhibit normal bone mineralization—leading to the paradoxical appearance of osteomalacia—can be understood in the context of these differential effects of $1,25(OH)_2D$ on the osteoblast as it differentiates. Excess $1,25(OH)_2D$ can disrupt the differentiation pathway.

C. Actions of vitamin D in kidney   The kidney expresses VDRs, and $1,25(OH)_2D$ stimulates the expression of calbindin, TRPV5 (the renal homologue of the intestinal TRPV6), and Ca^{2+}-ATPase (PMCA) in the distal tubule as well as $24,25(OH)_2D$ production in the proximal tubule. However, the role of $1,25(OH)_2D$ in regulating calcium and phosphate transport across the renal epithelium remains controversial. $25(OH)D$ may be more important than $1,25(OH)_2D$ in acutely stimulating calcium and phosphate reabsorption by the kidney tubules. *In vivo* studies are complicated by the effect of $1,25(OH)_2D$ on other hormones, particularly PTH, which appears to be more important than the vitamin D metabolites in regulating calcium and phosphate handling by the kidney.

D. Actions of vitamin D in other tissues   An exciting observation is that VDRs are found in a large number of tissues beyond the classic target tissues—gut, bone, and kidney—and these tissues respond to $1,25(OH)_2D$. Furthermore, many of these tissues express *CYP27B1* (the 1-hydroxylase) and so are capable of producing their own $1,25(OH)_2D$ from circulating $25(OH)D$. These tissues include elements of the hematopoietic and immune systems; cardiac, skeletal, and smooth muscle; and brain, liver, breast, endothelium, skin (keratinocytes, melanocytes, and fibroblasts), and endocrine glands (pituitary, parathyroid, pancreatic islets [beta cells], adrenal cortex and medulla, thyroid, ovary, and testis). Furthermore, malignancies developing in these tissues often contain VDRs and respond to the antiproliferative actions of $1,25(OH)_2D$.

The responses of these tissues to $1,25(OH)_2D$ are as varied as the tissues themselves. $1,25(OH)_2D$ regulates hormone production and secretion, including stimulation of insulin secretion from the pancreas and prolactin from the pituitary, but inhibiting PTH secretion from the parathyroid gland, renin secretion from the kidney, and atrial naturetic peptides from the heart. $1,25(OH)_2D$ enables the innate immune system by inducing antimicrobial peptides such as cathelicidin but suppresses the adaptive immune response by blocking the maturation of dendritic cells and shifting the balance of T-helper cell differentiation from Th1 and Th17 to Th2 and Treg. Myocardial contractility and vascular tone are modulated by $1,25(OH)_2D$. $1,25(OH)_2D$ reduces the rate of proliferation of many cell lines, including normal keratinocytes, fibroblasts, lymphocytes, and thymocytes as well as abnormal cells of mammary, skeletal, intestinal, lymphatic, and myeloid origin. Differentiation of numerous normal cell types, including keratinocytes, lymphocytes, hematopoietic cells, intestinal epithelial cells, osteoblasts, and osteoclasts as well as abnormal cells of the same lineage is enhanced by $1,25(OH)_2D$. Thus, the potential for manipulating a vast array of physiologic and pathologic processes with calcitriol and its analogs is enormous. This promise is being realized in that vitamin D analogs are being used to treat psoriasis, uremic hyperparathyroidism, and osteoporosis. Epidemiologic and animal studies indicate a role for vitamin D in the prevention and treatment of both type 1 and type 2 diabetes mellitus, autoimmune diseases such as multiple sclerosis and inflammatory bowel disease, and infections such as tuberculosis. Trials of vitamin D analogs in the treatment of a variety of cancers are also being conducted. Thus, although regulation of bone mineral homeostasis remains the major physiologic function of vitamin D and its metabolites, clinical applications for these compounds and their analogs are being evaluated outside the classic target tissues.

HOW VITAMIN D AND PTH CONTROL MINERAL HOMEOSTASIS

Consider a person who switches from a high normal to a low normal intake of calcium and phosphate—from 1200 mg/d to 300 mg/d of calcium (the equivalent of leaving three glasses of milk out of the daily diet). The net absorption of calcium falls sharply, causing a transient decrease in the serum calcium level. The homeostatic response to this transient hypocalcemia is led by an increase in PTH, which stimulates the release of calcium and phosphate from bone and the retention of calcium by the kidney. The phosphaturic effect of PTH allows elimination of phosphate, which is resorbed from bone together with calcium. In addition, the increase in PTH, along with the fall in serum calcium and serum phosphate, activates renal $1,25(OH)_2D$ synthesis. In turn, $1,25(OH)_2D$ increases the fractional absorption of calcium and further increases bone resorption. External calcium balance is thus restored by increased fractional absorption of calcium and increased bone resorption at the expense of higher steady state levels of PTH and $1,25(OH)_2D$.

MEDULLARY CARCINOMA OF THE THYROID

MCT, a neoplasm of thyroidal C cells, accounts for 3% to 5% of all thyroid malignancies. Approximately 75% of MCTs are sporadic. The remainder is familial and associated with one of three heritable syndromes: familial isolated MCT; multiple endocrine neoplasia 2A (MEN 2A), consisting of MCT, pheochromocytoma, and primary hyperparathyroidism; or multiple endocrine neoplasia 2B (MEN 2B), consisting of MCT, pheochromocytoma, multiple mucosal neuromas and, very rarely, primary hyperparathyroidism (Table 8–4). The MEN syndromes are more extensively discussed in Chapter 22.

The pathogenesis of hereditary MCT is largely due to the consequences of mutations in the *RET* proto-oncogene located on chromosome 10q11.2. *RET* (rearranged during transfection) encodes a membrane tyrosine kinase receptor whose ligands belong to the glial cell line-derived neurotrophic factor (GDNF) family. This receptor is expressed developmentally in migrating neural crest cells that give rise to hormone-secreting neuroendocrine cells (eg, C cells and adrenal medullary cells) and to the parasympathetic and sympathetic ganglia of the peripheral nervous system. Remarkably, different mutations in *RET* can produce five distinct diseases (see Table 8–4). Inheritance of certain activating mutations in *RET* is responsible for MEN 2A and familial MCT. Inheritance of a different set of activating mutations causes MEN 2B. In over half of sporadic MCTs, the tumor has a clonal somatic mutation (present in the tumor but not in genomic DNA), which is identical to one of the mutations responsible for the familial forms of MCT. These somatic mutations clearly play a causative role in sporadic MCT. Mutations in *RET* can also produce Hirschsprung disease, a congenital absence of the enteric parasympathetic ganglia, that can lead to a disturbance in intestinal motility, resulting in megacolon.

TABLE 8–4 Clinical presentations resulting from RET mutations.

Disorder	Characteristic Components
MEN 2A	MCT, pheochromocytoma, primary hyperparathyroidism
MEN 2A with lichen amyloidosis	MEN 2A + pruritic lesions of upper back
Familial MCT	MCT
MEN 2A or Familial MCT and Hirschsprung disease	MCT, Hirschsprung disease
MEN 2B	MCT, pheochromocytoma, marfanoid habitus, intestinal and mucosal ganglioneuromatosis

Modified with permission from Brandi ML, et al. Guidelines for diagnosis and therapy of MEN type 1 and type 2. *J Clin Endocrinol Metab*. 2001 Dec;86(12): 5658-5671.

MCT is usually located in the middle or upper portions of the thyroid lobes. It is typically unilateral in sporadic cases but often multicentric and bilateral in familial forms of the disease. The natural history of MCT is variable. Sporadic tumors may be quite aggressive or very indolent; the mean 5-year survival rate is about 50%. The behavior of familial forms varies among syndromes. MEN 2B has the most aggressive form of MCT, with a 2-year survival of about 50%; MEN 2A has a course similar to that of sporadic forms of this tumor, and familial MCT has the most indolent course of all MCT. The natural history of the tumor in familial MCT, MEN 2A, and MEN 2B syndromes has been dramatically impacted by early prophylactic total thyroidectomy that is now advised in most carriers of disease-causing *RET* mutations. MCT may spread to regional lymph nodes or undergo hematogenous spread to the lungs and other viscera. When metastatic, this tumor is sometimes associated with a chronic diarrhea syndrome. The pathogenesis of the diarrhea is unclear. In addition to CT, these tumors secrete a variety of other bioactive products, including prostaglandins, serotonin, histamine, and peptide hormones (ACTH, somatostatin, corticotropin-releasing hormone). In some cases, the associated diarrhea responds dramatically to treatment with a long-acting somatostatin analog such as octreotide, which blocks secretion of these bioactive products.

CT is a tumor marker for MCT. It is most sensitive for this purpose when secretion is stimulated with provocative agents. Provocative tests have used pentagastrin (0.5 ug/kg intravenously over 5 seconds) or a rapid infusion of calcium gluconate (2 mg calcium/kg over 1 minute). Blood samples are obtained at baseline and 1, 2, and 5 minutes after the stimulus. For maximal sensitivity, both tests are usually combined, with the calcium infusion immediately followed by administration of pentagastrin. Although basal CT levels are often normal in early tumors, CT levels may be many times higher than normal in patients with disseminated MCT. Despite this, the patients are uniformly normocalcemic. Although tumors secrete larger molecular weight forms of CT with decreased biologic activity, monomeric CT levels are often high as well. *RET* oncogene analysis has replaced provocative testing in familial MCT, although basal CT levels are still used to follow disease burden postoperatively and during chemotherapy trials.

Members of families carrying *RET* mutations must be screened for MCT and, if positive, for the associated tumors that occur in MEN 2A and MEN 2B (see Table 8–4 and Chapter 22). In the case of MCT, the presence of the *RET* mutation in an individual generally leads to the recommendation for a total thyroidectomy prior to the development of frank malignancy or abnormal CT levels. It is recommended in a kindred with a known *RET* mutation that children be screened at birth for the carrier state. Total thyroidectomy with or without central compartment lymph node dissection can be performed in mutation carriers, and further testing can be discontinued in genetically normal family members. The timing of prophylactic thyroidectomy in carriers of *RET* mutations, however, depends on the genotype present (ie, codon mutated in *RET*) (Table 8–5). As supported by the genotype-phenotype correlations in these diseases, surgery is recommended

Abbreviations: ATA, American Thyroid Association; MEN, multiple endocrine neoplasia; FMCT, familial medullary carcinoma of thyroid; MCT, medullary carcinoma of thyroid; HPT, primary hyperparathyroidism; PHEO, pheochromocytoma; dup, duplication.

Penetrance for the disorder:

***most cases, **few cases, *rare.

A, may delay surgery beyond 5 years of age if certain criteria are met; B, consider surgery before age 5 years and may delay if certain criteria are met; C, surgery before 5 years of age; D, surgery as soon as possible within the first year of life. Consultation with current ATA Guidelines for the most updated information is recommended. Criteria used to consider surgical timing are having a normal annual basal and/or stimulated serum calcitonin level and cervical ultrasound and possessing a family history of less aggressive MCT.

Data from American Thyroid Association Guidelines Task Force, Kloos RT, Eng C, et al. Medullary thyroid cancer: management guidelines of the American Thyroid Association. *Thyroid.* 2009 Jun;19(6):565-612.

in certain high-risk cases before 1 year of age, in cases of intermediate risk before 5 years of age, and in lower-risk patients later in childhood usually by 10 years of age. Because a limited number of mutations in *RET* cause more than 95% of hereditary MCT and up to 25% of sporadic disease, it is possible to screen the majority of patients using commercial reference laboratories.

Apparent sporadic MCT also calls for genetic testing and family studies. Up to 25% of new cases of MCT may actually be probands of families who harbor one of the familial syndromes. It has been noted in some kindreds, after careful and lengthy follow-up, that some individuals develop pheochromocytomas or primary hyperparathyroidism. Therefore, patients with

apparent familial MCT should be followed indefinitely for one of these components of MEN 2A. Screening of family members can be accomplished by genetic testing, once the index case is identified. Identification of a mutation that is present only in tumor tissue would establish the mutation as somatic and the tumor as a sporadic one. Identification of the same *RET* mutation in tumor and genomic DNA would make the diagnosis of a familial form of the disorder and would mandate careful screening of the family.

HYPERCALCEMIA

Clinical Features

A number of symptoms and signs accompany hypercalcemia. They include central nervous system effects such as lethargy, depression, psychosis, ataxia, stupor, and coma; neuromuscular effects such as weakness, proximal myopathy, and hypertonia; cardiovascular effects such as hypertension, bradycardia (and eventually asystole), and a shortened QT interval; renal effects such as stones, decreased glomerular filtration, polyuria, hyperchloremic acidosis, and nephrocalcinosis; gastrointestinal effects such as nausea, vomiting, constipation, and anorexia; eye findings such as band keratopathy; and systemic metastatic calcification. Primary hyperparathyroidism, one of the most common etiologies for hypercalcemia, has the mnemonic for recalling its signs and symptoms as *stones, bones, abdominal groans,* and *psychic moans* (Figure 8–12).

TABLE 8–6 Causes of hypercalcemia.

Primary Hyperparathyroidism
Sporadic
Associated with MEN 1 or MEN 2A
Familial
Postrenal transplantation
Variant Forms of Hyperparathyroidism
Familial hypocalciuric hypercalcemia
Lithium therapy
Tertiary hyperparathyroidism in chronic renal failure
Malignancies
Humoral hypercalcemia of malignancy
Caused by PTHrP (solid tumors, adult T-cell leukemia syndrome)
Caused by 1,25(OH)$_2$D (lymphomas)
Caused by ectopic secretion of PTH (rare)
Local osteolytic hypercalcemia (multiple myeloma, leukemia, lymphoma)
Sarcoidosis or Other Granulomatous Diseases
Endocrinopathies
Thyrotoxicosis
Adrenal insufficiency
Pheochromocytoma
VIPoma
Drug Induced
Vitamin A intoxication
Vitamin D intoxication
Thiazide diuretics
Lithium
Milk-alkali syndrome
Estrogens, androgens, tamoxifen (in breast carcinoma)
Immobilization
Acute Renal Failure
Idiopathic Hypercalcemia of Infancy
ICU Hypercalcemia
Serum Protein Disorders

Mechanisms

Although many disorders are associated with hypercalcemia (Table 8–6), they produce it by a limited number of mechanisms: (1) increased bone resorption, (2) increased gastrointestinal absorption of calcium, or (3) decreased renal excretion of calcium. Although any of these mechanisms can be involved in a given patient, the common feature of virtually all hypercalcemic disorders is accelerated bone resorption. The only hypercalcemic disorder in which bone resorption does not play a part is the milk-alkali syndrome.

The central feature of the defense against hypercalcemia is suppression of PTH secretion. This reduces bone resorption, renal production of 1,25(OH)$_2$D, and, thereby, intestinal calcium absorption and increases urinary calcium losses. The kidney plays a key role in the adaptive response to hypercalcemia as the only route of net calcium elimination. The level of renal calcium excretion is markedly increased by the combined effects of an increased filtered load of calcium and the suppression of PTH. However, the patient who relies on the kidneys to excrete an increased calcium load is in precarious balance. Glomerular filtration is impaired by
FIGURE 8–13 Vicious cycle of hypercalcemia. Once established, hypercalcemia can be maintained or aggravated as depicted. (Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism*, 3rd ed. New York: McGraw-Hill Education; 1995.)

hypercalcemia; the urinary concentrating ability is diminished, predisposing to dehydration; poor mentation may interfere with access to fluids; and nausea and vomiting may further predispose to dehydration and renal azotemia. Renal insufficiency, in turn, compromises calcium clearance, leading to a downward spiral (Figure 8–13). Thus, once established, many hypercalcemic states are self-perpetuating or aggravated through the *vicious cycle of hypercalcemia*. The only alternative to the renal route for

elimination of calcium from the extracellular fluid is deposition of calcium phosphate and other salts in bone and soft tissues. Soft tissue calcification is observed with massive calcium loads, with massive phosphate loads (as in tumor lysis syndrome, crush injuries and compartment syndromes), and when renal function is markedly impaired and the calcium-phosphate product rises.

Differential Diagnosis

As a practical matter, the categories for differential diagnosis are primary hyperparathyroidism and *everything else* (see Table 8–6). Hyperparathyroidism is by far the most common cause of outpatient hypercalcemia and has distinctive pathophysiologic features. Thus, the first step in the differential diagnosis is determination of intact PTH (Figure 8–14). If the PTH level is high, and thus inappropriate for hypercalcemia, little further workup is required except to consider the variant forms of hyperparathyroidism that are discussed later. If the PTH level is suppressed, then a search for other entities must be conducted. Most other entities in Table 8–6 are readily diagnosed by their distinctive features, as discussed later.

DISORDERS CAUSING HYPERCALCEMIA

1. PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism results from the excessive secretion of PTH and typically produces frank hypercalcemia. With routine screening of serum chemistries, we have come to recognize that primary hyperparathyroidism is a common and usually asymptomatic disorder. Its incidence is approximately 42 per 100,000, and its prevalence is up to 4 per 1000 in women over age 60. Primary hyperparathyroidism is approximately 2 to 3 times more common in women than in men.

Etiology and Pathogenesis

Primary hyperparathyroidism is caused by a single parathyroid adenoma in about 80% to 85% of cases and by primary hyperplasia of the parathyroids in 10% to 15%. Parathyroid carcinoma is a rare cause of hyperparathyroidism, accounting for 1% to 2% of cases. Parathyroid carcinoma is often recognizable preoperatively because it presents with severe hypercalcemia or a palpable neck mass.

Sporadic parathyroid adenomas have a clonal origin, indicating that they can be traced back to an oncogenic mutation in a single progenitor cell. A few of these genetic alterations have been identified and/or assigned to chromosomal loci. About 12% to 35% of sporadic parathyroid adenomas have inactivating mutations in the tumor suppressor gene *MENIN* (11q12-13). As reviewed later and in Chapter 22, loss of menin function is the cause of parathyroid, pituitary, and pancreatic tumors in the MEN 1 syndrome. An additional 40% of parathyroid adenomas display allelic loss on chromosome 1p (1p32pter).

Another important locus (11q13) has been implicated in approximately 8% of sporadic parathyroid adenomas and involves the *cyclin D1* gene. In the initial elucidation of this pathogenic mechanism, a chromosomal rearrangement was found in a parathyroid tumor. Breakage and then inversion of a piece of chromosome 11 led to the expression of cyclin D1, a cell-cycle regulatory protein, under the control of the PTH promoter. As expected, this promoter is highly active in parathyroid cells, resulting in marked overexpression of cyclin D1 in these tumor cells. Cyclin D1 is normally expressed at high levels in the G_1 phase of the cell cycle and permits entry of cells into the mitotic phase of the cycle. Thus, a parathyroid-specific disorder of cell-cycle regulation leads to abnormal cell proliferation and ultimately excessive PTH production.

Parathyroid hyperplasia accounts for 12% to 15% of cases of primary hyperparathyroidism and is the pathologic basis for these inherited conditions: MEN 1, MEN 2A, the hyperparathyroidism-jaw tumor (HPT-JT) syndrome, and isolated familial hyperparathyroidism. In all of these instances four or fewer glands may be involved at the time of presentation, or the hyperparathyroidism can occur in different glands asynchronously. Inheritance of all of these conditions is autosomal dominant.

Parathyroid hyperplasia appears to share similar pathogenic mechanisms with parathyroid adenomas. The MEN 1 syndrome illustrates this. MEN 1 is due to the inherited inactivation of one allele of *MENIN*, a tumor suppressor. Acquired postnatal somatic mutations in the remaining *MENIN* allele result in loss of that allele's function as well. This leads to tumors in those endocrine tissues in which the gene is expressed. In this view, multicentric somatic mutations would account for the occurrence of 4-gland hyperparathyroidism.

Menin is a key cellular protein responsible for transcriptional control and regulation of the cell cycle and other pathways important in cell growth. Over 1000 mutations have been uncovered in *MENIN* accounting for cases of MEN 1. Approximately 10% of MEN 1 cases are due to new mutations.

Kindreds with a presentation like MEN 1 but without mutations in *MENIN* have been investigated for germline mutations in cyclin-dependent kinase inhibitors (CDKIs) of which there are seven known genes. In an analysis of 196 consecutive cases of MEN 1 or other tumor states without germline mutations in *MENIN*, one laboratory found seven probable pathologic mutations in these genes. Three of the seven mutations were in *p27* with the remainder in three other CDKIs (*p15, p18,* and *p27*). These mutations are hypothesized to be disease-causing based on *in vitro* studies. The altered sequences in the CDKI protein can alter the downstream interactions they have with other proteins (such as the adaptor protein GRB2) or can alter protein stability and/or degradation. The CDKIs negatively control the cell cycle through interaction with and inhibition of cyclins D, E, and A. Germline mutations in kindreds would, therefore, involve loss of function in known inhibitors of cell growth and cell cycle activity.

In MEN 2A, parathyroid hyperplasia can occur due to activating mutations of *RET* in the four parathyroid glands. A *RET* mutation at codon 634 is one that predisposes to the development of primary hyperparathyroidism. Only 10% to 30% of patients with MEN 2A develop primary hyperparathyroidism.

In addition to classical MEN 1, germline mutations in *MENIN* have been identified in a subset of cases of familial isolated hyperparathyroidism. This observation established the concept that isolated familial hyperparathyroidism is an allelic variant of MEN 1 missing the tumors in the other endocrine glands. Other cases of familial isolated hyperparathyroidism are explained, albeit rarely, by mutations in *CDC73* the gene that causes the HPT-JT syndrome (discussed later). Additional families with isolated hyperparathyroidism have, as yet, no identified mutations.

In contrast to MEN 1 and MEN 2A, both benign and malignant parathyroid tumors occur in the HPT-JT syndrome. This is an autosomal dominant disorder that includes primary hyperparathyroidism (90%), jaw tumors (ossifying fibromas of the mandible or maxilla) (30%), renal cysts (10%), and less frequently renal hamartomas and Wilms tumor. Linkage analysis originally determined the locus for this syndrome, which had been designated as *hyperparathyroidism 2 or HRPT2* to be at 1q24-q32. Inactivating mutations in the tumor suppressor *CDC73*, encoding the protein parafibromin, have been identified in HPT-JT kindreds. These mutations inactivate parafibromin, a protein that plays a role in transcriptional regulation and chromatin modification.

In the HPT-JT syndrome, both single- and multiple-gland disease have been noted. It was further noted that approximately 15% of affected individuals with HPT-JT syndrome develop parathyroid cancer, instead of adenomas or hyperplasia, suggesting that reduced parafibromin function also contributes to a malignant phenotype. Several groups have shown that a large percentage (~70%) of patients with sporadic parathyroid cancer harbor somatic mutations in *CDC73*. Surprisingly, approximately 30% of individuals with isolated parathyroid cancer have also been found to have germline mutations in *CDC73* without the other manifestations of the HPT-JT syndrome. It is now thought that the majority of sporadically occurring parathyroid cancers are due to somatic mutations in the coding region of this gene. A pathologic study of more than 50 cases of parathyroid cancer indicates that the loss of parafibromin immunoreactivity is a specific and key feature of malignancy with a sensitivity of 96% (CI, 85%-99%) and specificity of 99% (CI, 92%-100%).

Clinical Features

A. Symptoms and signs

The typical clinical presentation of primary hyperparathyroidism has evolved considerably over the past few decades. As the disease continues to be detected by screening that includes determination of serum calcium levels, there has been a marked reduction in the frequency of the classic signs and symptoms of primary hyperparathyroidism. Renal disease (stones, decreased renal function, and occasionally nephrocalcinosis) and the classic hyperparathyroid bone disease osteitis fibrosa cystica are decidedly rare today. In fact, about 85% of patients presenting today have neither bone nor renal manifestations of hyperparathyroidism and are regarded as asymptomatic or at most minimally symptomatic. At the same time, we have begun to recognize more subtle manifestations of hyperparathyroidism. This has presented a number of questions about the role of parathyroid surgery in primary hyperparathyroidism, which are discussed later (see Treatment).

1. **Hyperparathyroid bone disease**—The classic bone disease of hyperparathyroidism is osteitis fibrosa cystica. Formerly common, this disorder now occurs in less than 10% of patients. Clinically, osteitis fibrosa cystica causes bone pain and sometimes pathologic fractures. The most common laboratory finding is an elevation of the alkaline phosphatase level, reflecting high bone turnover. Histologically, there is an increase in the number of bone-resorbing osteoclasts, marrow fibrosis, and cystic lesions that may contain fibrous tissue (brown tumors). The most sensitive and specific radiologic finding of osteitis fibrosa cystica is subperiosteal resorption of cortical bone, best seen in high-resolution films of the phalanges (Figure 8–15A). A similar process in the skull leads to a salt-and-pepper appearance (Figure 8–15B). Bone cysts or brown tumors may present as osteolytic lesions. Dental films may disclose loss of the lamina dura of the teeth, but this is a nonspecific finding also seen in periodontal disease.

    The other important skeletal consequence of hyperparathyroidism is osteoporosis or low bone mass. Unlike other osteoporotic disorders, hyperparathyroidism often results in the preferential loss of cortical bone (Figure 8–16). In general, both the mass and mechanical strength of trabecular bone are relatively maintained in mild primary hyperparathyroidism. Patients who are followed medically with this disease generally do not experience progressive bone loss for as long as 8 years after diagnosis (Figure 8–17). This may be due to the fact that mild PTH excess has an anabolic effect on the skeleton to maintain or even increase bone mass. However, longer medical
FIGURE 8–15   A. Magnified x-ray of index finger on fine-grain industrial film showing classic subperiosteal resorption in a patient with severe primary hyperparathyroidism. Note the left (radial) surface of the distal phalanx, where the cortex is almost completely resorbed, leaving only fine wisps of cortical bone. **B.** Skull x-ray from a patient with severe secondary hyperparathyroidism due to end-stage renal disease. Extensive areas of demineralization alternate with areas of increased bone density, resulting in the "salt and pepper" skull x-ray. (Used with permission from Dr. Harry Genant.)
FIGURE 8–16 Bone mineral density at several sites in primary hyperparathyroidism shown as the percentage of expected for age. (Adapted with permission from Silverberg SJ, et al. Nephrolithiasis and bone involvement in primary hyperparathyroidism. *Am J Med.* 1990 Sep;89(3):327-334.)

follow-up of patients with mild primary hyperparathyroidism (10-15 years) demonstrates that bone mineral density (BMD) by dual energy x-ray absorptiometry (DXA) declines significantly at the hip and forearm. Osteoporosis, defined by BMD T-scores by DXA (–2.5 or lower) is generally considered to be an indication for surgical treatment of primary hyperparathyroidism (see Treatment).

2. **Hyperparathyroid kidney disease**—Once common in primary hyperparathyroidism, kidney stones now occur in 10% to 20% of cases depending on the series. These are usually calcium oxalate stones. From the perspective of a stone clinic, only about 7% of calcium stone-formers prove to have primary hyperparathyroidism. They are difficult to manage medically, and stones constitute one of the agreed indications for parathyroidectomy. Surgical cure of primary hyperparathyroidism in patients who form stones produces a substantial reduction in future stone formation. Clinically evident nephrocalcinosis rarely occurs, but a gradual loss of renal function is not uncommon. Renal function is stabilized after a successful parathyroidectomy, and otherwise unexplained renal insufficiency (defined as an estimated glomerular filtration rate [eGFR] <60 mL/min) in the setting of primary hyperparathyroidism is also considered to be an indication for surgery because of the risk of progression. Chronic hypercalcemia can also compromise the renal concentrating ability, giving rise to polydipsia and polyuria and dehydration.

3. **Nonspecific features of primary hyperparathyroidism**—Although stupor and coma occur in severe hypercalcemia, the degree to which milder impairments of central nervous system function affect the typical patient with primary hyperparathyroidism is unclear. Lethargy, fatigue, depression, difficulty in concentrating, and personality changes may occur; however, some patients appear to benefit from parathyroidectomy. Frank psychosis also responds to surgery on occasion. Muscle weakness with characteristic electromyographic changes is also seen, and there is evidence from controlled clinical trials that surgery can improve muscle strength. A number of studies have examined quality of life (QOL) and psychological function in patients with primary hyperparathyroidism pre- and post-parathyroid surgery, compared to a medically followed group. Results vary as to whether QOL improves with surgery. It was

formerly thought that the incidence of hypertension was increased in primary hyperparathyroidism, but that condition appears not to be more common compared to age-matched controls, and parathyroidectomy appears to be of no benefit in curing hypertension. Dyspepsia, nausea, and constipation all occur, probably as a consequence of hypercalcemia, but there is probably no increase in the incidence of peptic ulcer disease. The articular manifestations of primary hyperparathyroidism include chondrocalcinosis in up to 5% of patients. Acute attacks of pseudogout, however, are less frequent.

B. Laboratory findings   Hypercalcemia is nearly universal in primary hyperparathyroidism, although the serum calcium sometimes fluctuates into the upper normal range. In patients with subtle hyperparathyroidism, repeated serum calcium measurements over a period of time may be required to establish the pattern of intermittent hypercalcemia. Both total and ionized calcium are elevated, and in most clinical instances there is no advantage to measuring the ionized calcium level. Patients with normocalcemic variant of primary hyperparathyroidism, in whom subtle vitamin D deficiency and malabsorption have been eliminated, are being recognized more frequently. In patients with primary hyperparathyroidism, the serum phosphorus level is low-normal (<3.5 mg/dL) or low (<2.5 mg/dL) because of the phosphaturic effect of PTH. A mild hyperchloremic metabolic acidosis may also manifest itself.

The diagnosis of primary hyperparathyroidism in a hypercalcemic patient can be made by determining the intact PTH level. As shown in Figure 8–14, an elevated or even upper-normal level of PTH is clearly inappropriate in a hypercalcemic patient and establishes the diagnosis of hyperparathyroidism or one of its variants—FHH or lithium-induced hypercalcemia. The reliability of the two-site intact PTH assay allows for the definitive diagnosis of primary hyperparathyroidism. In a patient with a high PTH level, there is no need to screen for such disorders as metastatic cancer or sarcoidosis. Determinations of BMD, renal function, and renal imaging [abdominal radiograph, ultrasound, computed tomography (CT) scan] for renal stones are often obtained for clinical decision-making reasons. A determination of the ratio of calcium clearance and creatinine clearance should always be obtained to help to exclude FHH from consideration, particularly in the asymptomatic patient.

Treatment

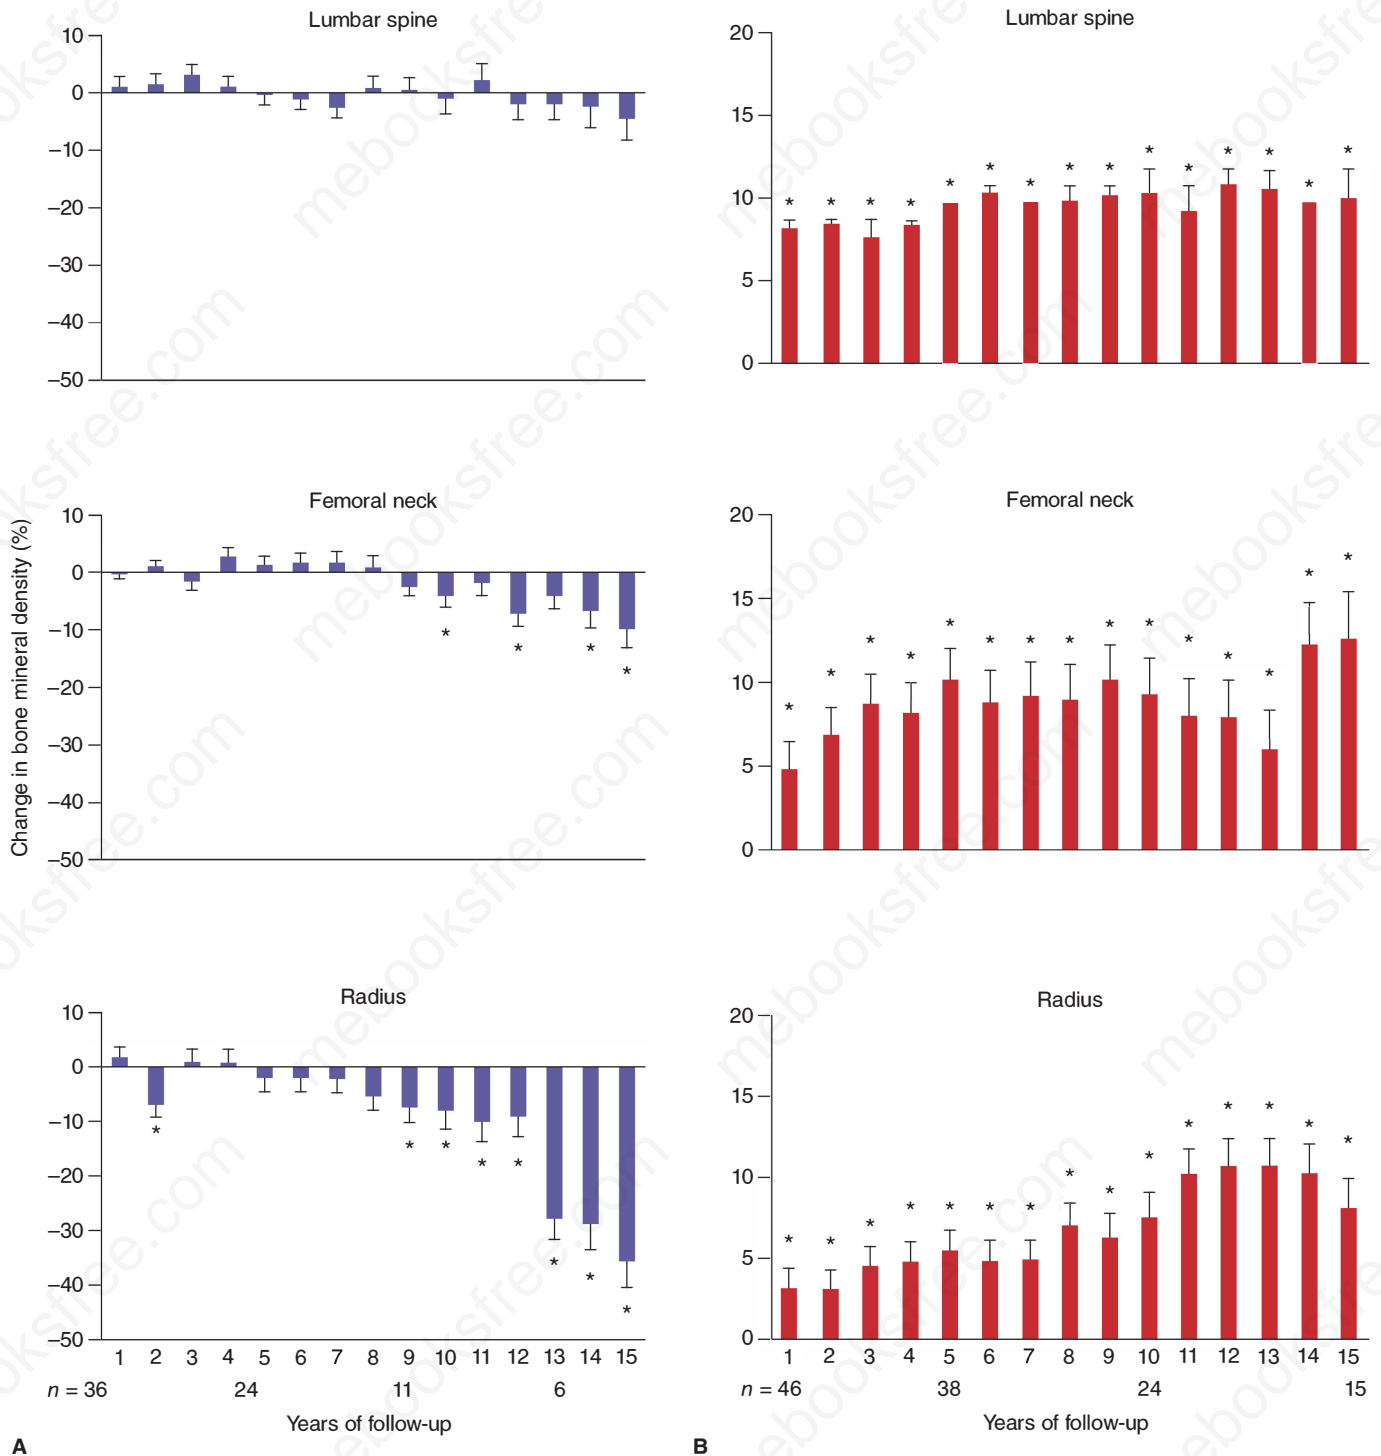
The definitive treatment of primary hyperparathyroidism is parathyroidectomy. The surgical strategy (ie, minimally invasive vs bilateral neck exploration) depends on the ability of localizing studies such as sestamibi scanning and cervical ultrasound to identify one clearly abnormal gland and the availability of intraoperative PTH determinations to verify that the disease-producing lesion has been removed during surgery. If multiple enlarged glands are suspected, the likely diagnosis is parathyroid hyperplasia or double adenoma. In patients with hyperplasia, the preferred operation is a 3½ gland parathyroidectomy, leaving a remnant sufficient to prevent hypocalcemia. Double parathyroid adenomas are both removed in affected patients. The pathologist is of little


FIGURE 8–17 Mean changes in bone mineral density (BMD) measurements by dual-energy x-ray absorptiometry (DXA) in patients who underwent parathyroidectomy compared with medical follow-up during a 15-year observational study. BMD changes are reported compared with baseline and were statistically different from baseline (*$P < 0.05$). The number of patients whose measurements are included is shown underneath each time point. Either just before (distal 1/3 radius) or after 10 years of conservative follow-up (femoral neck) BMD measurements began to fall significantly, while lumbar spine BMD remained unchanged (**Panel A**). Patients who underwent parathyroidectomy demonstrated improved BMD which persisted during 15 years of follow-up (**Panel B**). (Reproduced with permission from Rubin MR[1], Bilezikian JP, McMahon DJ, et al. The natural history of primary hyperparathyroidism with or without parathyroid surgery after 15 years. *J Clin Endocrinol Metab*. 2008 Sep;93(9):3462-3470.)

help in distinguishing among adenoma and hyperplasia; both typically have a robust degree of cellularity. However, the percentage of fat cells in the gland(s) removed, especially if substantial suggests the gland is a normal one. The recurrence rate of hypercalcemia is high in patients who have parathyroid hyperplasia—particularly in those with MEN 1 or allelic variants of MEN 1 or the HPT-JT syndromes, because of the inherited propensity for tumor growth. In such cases, the parathyroid remnant can be removed from the neck and implanted in pieces in forearm muscles to allow for easy subsequent removal of some parathyroid tissue if hypercalcemia recurs.

In experienced hands, the cure rate for a single parathyroid adenoma is more than 95%. The success rate in primary parathyroid hyperplasia is somewhat lower, because of missed glands and recurrent hyperparathyroidism in patients with MEN syndromes. There is a 20% incidence of persistent or recurrent hypercalcemia. Parathyroidectomy in MEN 1 patients can be difficult. Normal parathyroid glands weigh only about 40 mg and may be located throughout the neck or upper mediastinum. It is mandatory not only to locate the abnormal parathyroid gland(s), but also to find the other gland or glands and determine whether or not they are normal in size. Complications of parathyroid surgery in general include damage to the recurrent laryngeal nerve, which passes close to the posterior thyroid capsule, and inadvertent removal or devitalization of all parathyroid tissue, producing permanent hypoparathyroidism. In skilled hands, the incidence of these complications is less than 1%. It is critical that parathyroid surgery be performed by a surgeon with specialized skill and experience (see Chapter 26).

Parathyroid gland localization studies and intraoperative PTH testing are critical components of the surgical management of patients with primary hyperparathyroidism. If localizing studies clearly indicate a single abnormal gland and if intraoperative PTH testing is available, surgical management generally consists of unilateral exploration with the removal of the single abnormal gland. Localization studies continue to be essential in the management of patients with recurrent or persistent hyperparathyroidism. The most successful procedures are ^{99m}Tc-sestamibi scanning, CT scanning (including 4-D CT), magnetic resonance imaging, and ultrasound. Individually, each has a sensitivity of 60% to 80% in experienced hands. Used in combination, they are successful in at least 80% of reoperated cases. Invasive studies, such as angiography and venous sampling, are reserved for the most difficult cases.

There is no definitive medical therapy for primary hyperparathyroidism. In postmenopausal women, estrogen therapy in high doses (1.25 mg of conjugated estrogens or 30-50 μg of ethinyl estradiol) produces an average decrease of 0.5 to 1 mg/dL in the serum calcium and an increase in BMD. The effects of estrogen are on the skeletal responses to PTH. PTH levels do not fall. Estrogen therapy is almost never used for this condition due to the potential for complications in postmenopausal women. Small clinical trials provide experience with oral bisphosphonates (eg, alendronate) and the selective estrogen response modulator (SERM) raloxifene in these patients. Treatment with alendronate for 1 or 2 years reduces biochemical markers of bone turnover and improves BMD by DXA, especially in the spine and also in the femoral neck,

compared to baseline values prior to treatment. Studies have shown that raloxifene, administered over several weeks, to postmenopausal women with mild primary hyperparathyroidism also reduces bone turnover markers significantly. Neither alendronate nor raloxifene have significant and/or persistent effects on serum calcium or intact PTH levels, nor is either agent approved for treatment of primary hyperparathyroidism by the U.S. Food and Drug Administration (FDA). Calcimimetic agents that activate the parathyroid CaSR offer an alternative to surgery for individuals who meet guidelines for surgical referral but who are too sick or unwilling to undergo surgery or in whom surgery has failed to cure their hyperparathyroidism. The calcimimetic cinacalcet is FDA-approved for the management of primary hyperparathyroidism in the United States with those indications and for the treatment of secondary hyperparathyroidism in patients with CKD on dialysis (discussed later). In small clinical trials, cinacalcet has been shown to normalize serum [Ca^{2+}] and raise serum phosphate with modest lowering of PTH levels in patients with mild asymptomatic primary hyperparathyroidism for up to 5 years of therapy. No significant changes in BMD by DXA were seen. Patients with moderate to severe primary hyperparathyroidism (serum [Ca^{2+}] >12.5 mg/dL) also responded to cinacalcet with lowering of serum [Ca^{2+}] from 12.7 ± 0.8 mg/dL at baseline by 1 mg/dL or greater in 88% of patients. QOL parameters also improved compared to baseline. Therapy targeted to the CaSR is an alternative for controlling hypercalcemia in these patients.

The relatively asymptomatic status of most patients with primary hyperparathyroidism today presents a dilemma. Which of them should be subjected to surgery? More information on the natural history of untreated primary hyperparathyroidism would help in resolving this uncertainty. Most observational studies lack long-term follow-up and appropriate control groups. However, one observational study of 15 years duration showed modest increases in serum [Ca^{2+}] (after 10 years) and slow but consistent downward trends in BMD at cortical sites (femoral neck and distal radius) (after 8-10 years of follow-up) (see Figure 8–17A). This study has challenged the skeletal safety of long-term observation of otherwise asymptomatic patients. On the other hand, surgery is usually curative. In experienced hands, surgery has a low morbidity rate. Although parathyroid surgery has a substantial initial cost, over the long term, the cost-benefit ratio may be favorable when compared with a lifetime or many years of medical follow-up. Moreover, there is a marked improvement in BMD after surgery (see Figure 8–17B), with sustained increases over 15 years postoperatively.

Consensus Development Conferences or International Workshops in 1990, 2002, 2008, and 2013 examined evidence and published recommendations for surgery in mild asymptomatic primary hyperparathyroidism and for conservative management. Current recommendations for surgery (2013) are: (1) serum [Ca^{2+}] greater than 1 mg/dL above the upper limits of normal; (2) BMD DXA T score less than –2.5 at the lumbar spine, total hip, femoral neck or one-third distal radius; (3) presence of vertebral fracture(s) by any imaging modality; (4) estimated glomerular filtration rate (eGFR) less than 60 mL/min; (5) 24 hour urine calcium excretion greater than 400 mg and increased stone risk by biochemical stone

risk analysis; (6) presence of nephrolithiasis or nephrocalcinosis by x-ray, ultrasound, or CT; (7) age less than 50 years. Patients with a coexisting illness complicating the management of hypercalcemia should also be considered for surgery.

Recommendations for medical monitoring of patients not undergoing surgery should include annual measurements of serum [Ca^{2+}], PTH, creatinine, and eGFR. If renal stones have occurred or are suspected, biochemical analyses of the urine and renal imaging should be done. Skeletal surveillance should include DXA scanning every 1 or 2 years or as clinically appropriate and/ or spinal x-rays.

Variants of Primary Hyperparathyroidism

A. Familial hypocalciuric hypercalcemia   Inherited as an autosomal dominant trait, this disorder is responsible for life-long generally asymptomatic hypercalcemia, first detectable in cord blood. Hypercalcemia is usually mild (10.5-12 mg/dL [2.7-3.0 mmol/L]) and is often accompanied by mild hypophosphatemia and hypermagnesemia. The PTH level is normal or slightly elevated, indicating that this is a PTH-dependent form of hypercalcemia. The parathyroid glands are normal in size or slightly enlarged. The most notable laboratory feature of the disorder is hypocalciuria, which nearly all patients demonstrate. The urinary calcium level is usually less than 50 mg/24 h, and the calcium/creatinine clearance ratio is usually less than 0.01 and calculated as follows:

$$\frac{\text{Urine calcium} \times \text{Serum creatinine}}{\text{Serum calcium} \times \text{Urine creatinine}}$$

Hypocalciuria is an intrinsic renal trait; it persists even in patients who have undergone total parathyroidectomy and become hypocalcemic.

Because FHH is typically asymptomatic and benign, the most important role of diagnosis is to distinguish it from primary hyperparathyroidism and avoid an unnecessary parathyroidectomy. If subtotal parathyroidectomy is performed, the serum calcium invariably returns shortly to preoperative levels; patients with FHH resist attempts to lower the serum calcium while functioning parathyroid tissue remains. Unfortunate patients with this condition who have undergone total parathyroidectomy are rendered hypoparathyroid and are dependent on treatment with calcium and vitamin D supplements.

The diagnosis must be considered in patients with asymptomatic mild hypercalcemia who are relatively hypocalciuric. However, an unequivocal diagnosis cannot be made biochemically because the serum and urinary calcium and PTH levels all overlap with typical primary hyperparathyroidism. Family screening and/ or genetic testing are part of the workup needed to confirm the diagnosis. The penetrance of the phenotype is essentially 100%, and affected family members are hypercalcemic throughout life, so if the proband has the disorder, each first-degree relative who is screened has a 50% chance of being hypercalcemic.

The majority of cases of FHH (60%-70%) are caused by loss-of-function mutations in the CaSR, and this is termed FHH type 1.

Loss of the functional output of one CaSR allele shifts the set-point for inhibition of PTH release to the right, producing hypercalcemia. The same receptor is expressed in the kidney, where it regulates renal calcium excretion. Recently, patients with the FHH phenotype (hypercalcemia and hypocalciuria) who did not harbor mutations in the *CaSR* were shown to have mutations in *G-alpha 11* (FHH type 2) and a subunit of an adapter protein complex 2σ1 subunit (*AP2S1*; FHH type 3). A large number of point mutations in different exons of the CaSR produce the FHH type 1 phenotype. Fewer mutations and probands with FHH 2 and 3 have been so far identified. However, these genetic disorders must be considered in the full molecular evaluation of a proband and family with the FHH phenotype, especially those who have demonstrated no response in serum calcium to parathyroidectomy. Acquired hypocalciuric hypercalcemia has been described in association with antibodies that interact with the CaSR and block the ability of high [Ca^{2+}] to suppress PTH.

A child of two parents with FHH type 1 may inherit a mutant allele from each parent, producing **neonatal severe hypercalcemia**, a life-threatening disorder in which failure to sense extracellular calcium causes severe hyperparathyroidism, requiring total parathyroidectomy soon after birth. Clinically significant hypercalcemia has also been seen in babies with heterozygous *CaSR* mutations, if the mutation produces a dramatic loss of function in the CaSR protein.

B. MEN syndromes   As noted earlier, primary hyperparathyroidism is a feature of both MEN 1 and MEN 2A (see also Chapter 22). The penetrance of primary hyperparathyroidism in MEN 1 is over 90% by age 40. Patients with the MEN 1 syndrome inherit a loss-of-function germline mutation in the tumor suppressor gene *MENIN* on chromosome 11q12-13. A mutation during mitosis of a parathyroid cell that resulted in loss of function in the remaining allele in that cell would abrogate the cell's growth control mechanism and permit clonal expansion of its progeny ultimately to generate the parathyroid tumor. A similar mechanism appears also to operate in a small fraction of sporadic parathyroid adenomas with 11q12-13 deletions.

The penetrance of primary hyperparathyroidism in MEN 2A is up to 35%. As discussed in the earlier section on MCT, the disorder is caused by activating mutations in *RET*, a gene encoding tyrosine kinase growth factor receptor. Evidently, the *RET* gene product is less important for growth of the parathyroids than for thyroid C cells, because the penetrance of primary hyperparathyroidism is fairly low and because (in MEN 2B) a separate class of activating *RET* mutations produces MCT and pheochromocytoma and very rarely primary hyperparathyroidism. The treatment for parathyroid hyperplasia in MEN 1 or MEN 2 is usually subtotal parathyroidectomy. The recurrence rate is higher than in sporadic parathyroid hyperplasia and may approach 50% in MEN 1.

C. Lithium therapy   Both in patients and in isolated parathyroid cells, exposure to extracellular lithium shifts the

set-point for inhibition of PTH secretion to the right. Clinically, this results in hypercalcemia and a detectable or elevated level of PTH. Lithium treatment can also produce hypocalciuria and thus can phenocopy FHH. Most patients with therapeutic lithium levels for bipolar affective disorder have a slight increase in the serum calcium level, and up to 10% become mildly hypercalcemic, with PTH levels that are high normal or slightly elevated. Lithium treatment can also unmask underlying primary hyperparathyroidism. It is difficult to diagnose primary hyperparathyroidism in a lithium-treated patient, particularly when temporary cessation of lithium therapy is difficult. However, the likelihood of underlying primary hyperparathyroidism is high when the serum calcium is greater than 11.5 mg/dL, and the decision to undertake surgery must be based on clinical criteria. Unfortunately, surgical cure of hyperparathyroidism rarely ameliorates the underlying psychiatric condition.

2. MALIGNANCY-ASSOCIATED HYPERCALCEMIA

Malignancy-associated hypercalcemia is the second most common form of hypercalcemia, with an incidence of 15 cases per 100,000 per year—about one-half the incidence of primary hyperparathyroidism. Approximately 20% of patients with cancer develop hypercalcemia, which is due to humoral mechanisms in 80% of patients and osseous metastases in the remaining 20%. Malignancy-associated hypercalcemia is much less prevalent than primary hyperparathyroidism, because most patients have such limited survival once this complication occurs. Nonetheless, malignancy-associated hypercalcemia is the most common cause of hypercalcemia in hospitalized patients. The clinical features and pathogenesis of malignancy-associated hypercalcemia are presented in Chapter 21. The treatment of nonparathyroid hypercalcemia is presented later.

3. SARCOIDOSIS AND OTHER GRANULOMATOUS DISORDERS

Hypercalcemia is seen in up to 10% of subjects with sarcoidosis. A higher percentage of patients with sarcoidosis have hypercalciuria, and that manifestation often predates the presentation of hypercalcemia. This is due to inappropriately elevated $1,25(OH)_2D$ levels and abnormal vitamin D metabolism. Lymphoid tissue and pulmonary macrophages from affected individuals contain 25(OH)D 1-hydroxylase activity that is not seen in normal individuals. The 1-hydroxylase enzyme, responsible for the overproduction of $1,25(OH)_2D$ in sarcoidosis, is the same as that in the kidney (CYP27B1). 1-Hydroxylase activity in these cells is not readily inhibited by calcium or $1,25(OH)_2D$, indicating a lack of feedback inhibition. Macrophages expressing the 1-hydroxylase in these patients do not express a normally functioning 24-hydroxylase so that the catabolism and clearance of $1,25(OH)_2D$ in these cells are lacking. This makes these subjects vulnerable to hypercalcemia or hypercalciuria during periods of increased vitamin D production (eg, summertime with increased sunlight exposure). γ-IFN stimulates 1-hydroxylase activity in these cells, which makes such subjects more vulnerable to altered calcium homeostasis when their disease is active. Glucocorticoids, on the other hand, suppress the inflammation, and subsequently 1-hydroxylase activity, as well as antagonize $1,25(OH)_2D$ action, providing effective treatment for both the disease and this complication of it.

Other granulomatous diseases are associated with abnormal vitamin D metabolism, resulting in hypercalcemia and/or hypercalciuria. These disorders include tuberculosis, berylliosis, disseminated coccidioidomycosis, histoplasmosis, leprosy, and pulmonary eosinophilic granulomatosis. Furthermore, a substantial number of subjects with Hodgkin or non-Hodgkin lymphomas develop hypercalcemia associated with inappropriately elevated $1,25(OH)_2D$ levels. In a recent series of 101 patients with elevated $1,25(OH)_2D$ levels and hypercalcemia, Donovan and colleagues found the leading causes to be sarcoidosis (49%), hematologic malignancies (17%), and infections (mainly mycobacterial, 8%). The median angiotensin-converting enzyme (ACE) levels in those with sarcoidosis were 218 U/L (interquartile range, 176-277; normal range 20-130 U/L). A level above the normal range did not reliably associate with sarcoidosis. Levels above 250 U/L, however, were specific (89%) but insensitive (31%). In addition, levels of $1,25(OH)_2D$ greater than 300 pmol/L (normal range, 40-150 pmol/L) were not observed in patients from this series with sarcoidosis. Although $1,25(OH)_2D$-mediated hypercalcemia is a rare occurrence, its etiology must be determined to select the most appropriate management.

4. ENDOCRINOPATHIES

Thyrotoxicosis

Mild hypercalcemia is found in about 10% of patients with thyrotoxicosis. The PTH level is suppressed, and the serum phosphate is in the upper normal range. The serum alkaline phosphatase and biochemical markers of bone turnover may be mildly increased. Significant hypercalcemia may develop in patients with thyrotoxicosis, particularly if it is severe and if patients are temporarily immobilized. Thyroid hormone has direct bone-resorbing properties causing a high turnover state, which often eventually progresses to mild osteoporosis.

Adrenal Insufficiency

Hypercalcemia can be a feature of acute adrenal crisis and responds rapidly to glucocorticoid therapy. Animal studies suggest that hemoconcentration is a critical factor. In experimental adrenal insufficiency, ionized $[Ca^{2+}]$ is normal.

5. ENDOCRINE TUMORS

Hypercalcemia in patients with pheochromocytoma may be a manifestation of primary hyperparathyroidism in MEN 2A. Hypercalcemia, however, is found occasionally in uncomplicated pheochromocytoma, paraganglioma, and other neuroendocrine

tumors where it appears to result from secretion of PTHrP by the tumor. About 40% of tumors secreting VIP (VIPomas) are also associated with hypercalcemia. The cause is unknown. It is known, however, that high levels of VIP may activate PTH/PTHrP receptors.

6. THIAZIDE DIURETICS

The administration of thiazides and related diuretics, such as chlorthalidone, metolazone, and indapamide, can produce an increase in the serum calcium that is not fully accounted for by hemoconcentration. Hypercalcemia is mild and usually transient, lasting for days or weeks, but occasionally it persists. Severe hypercalcemia is rare. In a retrospective series of patients with thiazide-induced hypercalcemia, 71% had persistent hypercalcemia after discontinuation of the drug. Primary hyperparathyroidism was diagnosed in 24% of those patients. Thiazide administration can also exacerbate the effects of underlying primary hyperparathyroidism.

7. VITAMIN D AND VITAMIN A

Hypervitaminosis D

Hypercalcemia may occur in individuals ingesting large doses of vitamin D either therapeutically or accidentally (eg, irregularities in milk product supplementation with vitamin D have been reported). The initial signs and symptoms of vitamin D intoxication include weakness, lethargy, headaches, nausea, and polyuria and are attributable to hypercalcemia and hypercalciuria. Ectopic calcification may occur, particularly in the kidneys, resulting in nephrolithiasis or nephrocalcinosis; other sites include blood vessels, heart, lungs, and skin. Infants appear to be quite susceptible to vitamin D intoxication and may develop disseminated atherosclerosis, supravalvular aortic stenosis, and renal acidosis.

Hypervitaminosis D is readily diagnosed by the very high serum levels of 25(OH)D, because the conversion of vitamin D to 25(OH)D is not tightly regulated. In contrast, $1,25(OH)_2D$ levels are often normal, but not suppressed. This reflects the expected feedback regulation of $1,25(OH)_2D$ production by the elevated calcium and reduced PTH levels. Levels of free $1,25(OH)_2D$ when measured have been found to be increased. This is in part caused by the high levels of 25(OH)D that displace $1,25(OH)_2D$ from DBP, raising the ratio of free:total $1,25(OH)_2D$. The elevated free concentration of $1,25(OH)_2D$, plus the intrinsic biologic effects of the elevated 25(OH)D concentration, combine to increase intestinal calcium absorption and bone resorption. The hypercalciuria, which is invariably seen, may lead to dehydration and coma as a result of hyposthenuria, prerenal azotemia, and worsening hypercalcemia due, in part, to decreased renal clearance.

The dose of vitamin D required to induce toxicity varies among patients, reflecting differences in absorption, storage, and subsequent metabolism of the vitamin as well as in target tissue response to the active metabolites. For example, an elderly patient is likely to have reduced intestinal calcium transport and renal production of $1,25(OH)_2D$. Such an individual may be able to tolerate 50,000 to 100,000 units of vitamin D daily (although these levels far exceed daily requirements). However, patients with unsuspected hyperparathyroidism receiving such doses for the treatment of osteoporosis are more likely to experience hypercalcemia. Treatment consists of withdrawing the vitamin D, rehydration, reducing calcium intake, and administering glucocorticoids, which antagonize the ability of $1,25(OH)_2D$ to stimulate intestinal calcium absorption. Excess vitamin D is slowly cleared from the body (weeks to months), so treatment is prolonged.

Hypervitaminosis A

Excessive ingestion of vitamin A, usually from self-medication with vitamin A preparations, causes a number of abnormalities, including gingivitis, cheilitis, erythema, desquamation, and hair loss. Bone resorption is increased, leading to osteoporosis and fractures, hypercalcemia, and hyperostosis. Excess vitamin A causes hepatosplenomegaly with hypertrophy of fat storage cells, fibrosis, and sclerosis of central veins. Many of these effects can be attributed to the effects of vitamin A on cellular membranes. Under normal circumstances, such effects are prevented because vitamin A is bound to retinol-binding protein (RBP), and its release from the liver is regulated. In vitamin A toxicity, however, these protective mechanisms are overcome, and retinol and its retinyl esters appear in blood unbound to RBP. The mechanism by which vitamin A stimulates bone resorption is not clear.

8. MILK-ALKALI SYNDROME

The ingestion of large quantities of calcium together with an absorbable alkali can produce hypercalcemia with alkalosis, renal impairment, and often nephrocalcinosis. The syndrome was more common when absorbable antacids were the standard treatment for peptic ulcer disease, but it is still seen occasionally. This is the only recognized example of pure absorptive hypercalcemia. The details of its pathogenesis are poorly understood.

9. MISCELLANEOUS CONDITIONS

Immobilization

In immobilized patients there is a marked increase in bone resorption, which often produces hypercalciuria and occasionally hypercalcemia, mainly in individuals with a preexisting high bone turnover state, such as adolescents and patients with thyrotoxicosis or Paget disease. Intact PTH and PTHrP levels are suppressed. The disorder remits with the restoration of activity. If acute treatment is required, bisphosphonates appear to be the treatment of choice.

Acute Renal Failure

Hypercalcemia is often seen when renal failure is precipitated by rhabdomyolysis and usually occurs during the early recovery stage, presumably as calcium deposits are mobilized from damaged muscle tissue. It typically resolves over a few weeks.

TREATMENT OF HYPERCALCEMIA

Initial management of hypercalcemia consists of assessing the hydration state of the patient and rehydrating as necessary with intravenous saline. The first goal is to restore renal function, which is often impaired in hypercalcemia because of reduced glomerular filtration and dehydration. Hypercalcemia impairs the urinary concentrating ability, leading to polyuria, and at the same time impairs the sensorium, diminishing the sense of thirst. Once renal function is restored, excretion of calcium can be further enhanced by inducing a saline diuresis. Because most of the filtered calcium is reabsorbed by bulk flow in the proximal tubule along with sodium chloride, a saline diuresis markedly increases calcium excretion. However, a vigorous saline diuresis also induces substantial urinary losses of potassium and magnesium, and these must be monitored and replaced as necessary.

In contemporary management, prolonged saline infusion has been supplanted by early institution, when safe, of intravenous bisphosphonate therapy. Chronic maintenance therapy may be started soon after hospitalization, once the diagnosis is secured, and adequate hydration and renal perfusion are established. The most useful agents for chronic hypercalcemia due to cancer are intravenous bisphosphonates (zoledronic acid or pamidronate), which can take up to 5 days to have their full effect. Bisphosphonates act by inhibiting osteoclastic bone resorption. The initial dose of pamidronate is 60 to 90 mg by intravenous infusion over 1 hour, and the dose of zoledronic acid is 4 mg infused over 15 minutes. In two large trials, 88% and 70% of patients with malignancy-associated hypercalcemia normalized their serum calcium values after infusions of zoledronic acid (4 mg) and pamidronate (90 mg), respectively. Zoledronic acid produced a longer duration of response when treating hypercalcemia of malignancy—32 days versus 18 days for pamidronate. The nadir of serum calcium does not occur until 4 to 5 days after administration of either agent. Retreatment with either agent can be conducted after recurrence of hypercalcemia. Transient fever and myalgia occur in between 10% and 20% of patients who undergo intravenous bisphosphonate therapy. Increases in serum creatinine of greater than or equal to 0.5 mg/dL occur in about 15% of patients. Intravenous bisphosphonates should be used cautiously (if at all) and at reduced doses when the baseline serum creatinine exceeds 2.5 mg/dL.

In patients with severe hypercalcemia and in those with renal insufficiency that is refractory to rehydration, it may be necessary to use an alternative second-line antiresorptive agent for a few days while awaiting the full therapeutic effect of intravenous bisphosphonates. For this purpose, synthetic salmon CT may be administered at a dose of 4 to 8 IU/kg subcutaneously every 12 hours. This is a useful adjunct acutely, but most patients become refractory to CT within days to weeks, so it is not suitable for chronic use.

In 33 patients with malignancy-associated hypercalcemia refractory to intravenous bisphosphonates (serum $[Ca^{2+}]$ >12.5 mg/dL), the neutralizing monoclonal antibody to receptor activator of nuclear factor kappa B ligand (RANK-L) denosumab demonstrated efficacy at controlling hypercalcemia. Patients were given denosumab (120 mg subcutaneously) on days 1, 8, 15, and 29 and then every 4 weeks. Using this treatment protocol, by day 10, 64% of patients achieved an albumin-corrected serum $[Ca^{2+}]$ of less than or equal to 11.5 mg/dL, while 33% of patients declined to less than or equal to 10.8 mg/dL. Throughout the study, 70% and 64% of patients achieved corrected serum $[Ca^{2+}]$ values of less than or equal to 11.5 mg/dL and less than or equal to 10.8 mg/dL, respectively, with a mean duration of response estimated to be 104 days. Thus, this agent is an additional therapy for refractory hypercalcemia in such patients.

Glucocorticoid administration is first-line treatment for hypercalcemia in patients with multiple myeloma, lymphoma, sarcoidosis, or intoxication with vitamin D or vitamin A. Glucocorticoids are also beneficial in some patients with breast carcinoma. However, they are of little use in most other patients with solid tumors and hypercalcemia.

HYPOCALCEMIA

Classification

Both PTH and $1,25(OH)_2D$ maintain a normal serum calcium and are thus central to the defense against hypocalcemia. Hypocalcemic disorders are best understood as failures of the adaptive response. Thus, chronic hypocalcemia can result from a failure to secrete PTH, altered responsiveness to PTH, a deficiency of vitamin D, or a resistance to vitamin D (Table 8–7). Acute hypocalcemia is most often the consequence of an overwhelming challenge to the adaptive response such as rhabdomyolysis, in which a flood of phosphate from injured skeletal muscle inundates the extracellular fluid.

Clinical Features

Most of the symptoms and signs of hypocalcemia occur because of increased neuromuscular excitability (tetany, paresthesias, muscle cramping, seizures, organic brain syndrome), and many of the complications of treatment of hypocalcemia result from the deposition of calcium in soft tissues (cataract, calcification of basal ganglia, nephrolithiasis, nephrocalcinosis, reduced renal function).

A. Neuromuscular manifestations Clinically, the hallmark of severe hypocalcemia is tetany. Tetany is a state of spontaneous tonic muscular contraction. Overt tetany is often heralded by tingling paresthesias in the fingers and around the mouth, but the classic muscular component of tetany is carpopedal spasm. This begins with adduction of the thumb, followed by flexion of the metacarpophalangeal joints, extension of the interphalangeal joints, and flexion of the wrists to produce the *main d'accoucheur* posture (Figure 8–18). These involuntary muscle contractions are painful. Although the hands are most typically involved, tetany can involve other muscle groups, including life-threatening spasm of laryngeal muscles (laryngospasm). Electromyographically, tetany is typified by repetitive motor neuron action potentials, usually grouped as doublets. Tetany is not specific for hypocalcemia. It also occurs with

hypomagnesemia and metabolic alkalosis, and the most common cause of tetany is respiratory alkalosis from hyperventilation.

Lesser degrees of neuromuscular excitability (eg, serum [Ca] 7.5-8.5 mg/dL) produce latent tetany, which can be elicited by
FIGURE 8–18   Position of fingers in carpal spasm due to hypocalcemic tetany. (Reproduced with permission from Ganong WF. *Review of Medical Physiology.* 16th ed. New York: McGraw-Hill Education; 1993.)

testing for Chvostek and Trousseau signs. Chvostek sign is elicited by tapping the facial nerve about 2 cm anterior to the earlobe, just below the zygoma. The response is a contraction of facial muscles ranging from twitching of the angle of the mouth to hemifacial contractions. The specificity of the test is low; about 25% of normal individuals have a mild Chvostek sign. Trousseau sign is elicited by inflating a blood pressure cuff to about 20 mm Hg above systolic pressure for 3 minutes. A positive response is carpal spasm. Trousseau sign is more specific than Chvostek, but 1% to 4% of normal individuals have positive Trousseau signs.

Hypocalcemia predisposes to focal or generalized seizures. Other central nervous system effects of hypocalcemia include pseudotumor cerebri, papilledema, confusion, lassitude, depression, organic brain syndrome, and coma. Twenty percent of children with chronic hypocalcemia develop mental retardation. The basal ganglia are often calcified in patients with longstanding hypoparathyroidism or PHP. This is usually asymptomatic but may produce a variety of movement disorders.

B. Other manifestations of hypocalcemia

1. **Cardiac effects**—Repolarization is delayed, with prolongation of the QT interval. Excitation-contraction coupling may be impaired, and refractory congestive heart failure is sometimes observed, particularly in patients with underlying cardiac disease.
2. **Ophthalmologic effects**—Subcapsular cataract is common in chronic hypocalcemia, and its severity is correlated with the duration and level of hypocalcemia.
3. **Dermatologic effects**—The skin is often dry and flaky and the nails brittle.

CAUSES OF HYPOCALCEMIA

1. HYPOPARATHYROIDISM

Hypoparathyroidism may be surgical, autoimmune, familial/genetic, or idiopathic. The signs and symptoms are those of chronic hypocalcemia. Biochemically, the hallmarks of hypoparathyroidism are hypocalcemia, hyperphosphatemia (because the phosphaturic effect of PTH is lost), and an inappropriately low or undetectable PTH level.

Surgical Hypoparathyroidism

The most common cause of hypoparathyroidism is surgery on the neck, with removal or destruction of the parathyroid glands. The operations most often associated with hypoparathyroidism are cancer surgery (typically for laryngeal cancer), total thyroidectomy, and parathyroidectomy, but the skill and experience of the surgeon are more important predictors than the nature of the operation. Tetany ensues 1 or 2 days postoperatively or even earlier, and about half of patients with postoperative tetany recover sufficiently so they do not require long-term replacement therapy. In these cases, a devitalized parathyroid remnant has recovered its blood supply and resumes secretion of PTH. In some patients,

hypocalcemia may not become evident until years after the procedure.

In patients with severe hyperparathyroid bone disease preoperatively, a syndrome of postoperative hypocalcemia can follow successful parathyroidectomy. This is the "**hungry bone syndrome**," which results from avid uptake of calcium and phosphate by the bones. The parathyroids, although intact, cannot compensate. The syndrome is usually seen in patients with an elevated preoperative serum alkaline phosphatase and/or severe uremic secondary hyperparathyroidism. It can usually be distinguished from surgical hypoparathyroidism by the serum phosphorus, which is low in the hungry bones syndrome, because of skeletal avidity for phosphate, and high in hypoparathyroidism, and by the serum PTH, which becomes appropriately elevated in the hungry bone syndrome. This syndrome can be seen under any condition in which high levels of bone resorption are treated with an antiresorptive agent or even after thyroidectomy for severe hyperthyroidism.

Idiopathic Hypoparathyroidism

Acquired hypoparathyroidism is sometimes seen in the setting of polyendocrinopathies. Most commonly, it is associated with primary adrenal insufficiency and mucocutaneous candidiasis in the syndrome of *autoimmune polyendocrine syndrome type 1 (APS1)* (see Chapter 3). The typical age at onset of hypoparathyroidism is 5 to 9 years. A similar form of hypoparathyroidism can occur as an isolated finding. The age at onset of idiopathic hypoparathyroidism is 2 to 10 years, and there is a preponderance of female cases. Circulating autoantibodies are common in both APS1 and in isolated hypoparathyroidism. Many patients have antibodies that recognize the CaSR or react with NALP5 (NACHT leucine-rich-repeat protein 5), an intracellular signaling molecule expressed in the parathyroid. More important from the standpoint of pathogenesis are autoantibodies to type 1 interferons (IFNs, alpha and omega). Antibodies to these IFNs are present in nearly 100% of patients with APS1, often years before disease presentation, and can persist for years, making them the best markers for the disorder. Antibodies to interleukin (IL)-17 and IL-22 are also highly prevalent in APS1 patients. When tested in lab-based assays, these anticytokine antibodies (anti-IFN, anti-IL-17, IL-22) have neutralizing properties against these cytokines. However, exactly how these antibodies contribute to the pathogenesis of the immunologic alterations in APS1 patients *in vivo* is not completely clear. APS1 is an autosomal recessive (or rarely dominant) disorder due to mutations in the *AIRE* (autoimmune regulator) gene. AIRE is involved in the complex process of immune tolerance to self and is a key transcription factor in medullary thymic epithelial cells. AIRE promotes expression of thousands of tissue antigens enabling T cells autoreactive to these antigens to be deleted in the process of negative selection.

Another form of autoimmune hypoparathyroidism has been reported in patients with autoantibodies to the CaSR that functionally activate it and suppress PTH secretion. These rare cases have been detected along with other autoimmune disorders such as Addison disease and Hashimoto thyroiditis.

Familial Hypoparathyroidism

Hypoparathyroidism is an uncommon disorder and presents in familial forms transmitted as either autosomal dominant or recessive or X-linked traits. Autosomal recessive hypoparathyroidism occurs in families with *PTH* gene mutations that interfere with the normal processing of PTH. Another autosomal recessive form of this disease is due to a deletion of the 5' sequence of the gene encoding the transcription factor *glial cell missing 2*, which is necessary for parathyroid gland development. Hypoparathyroidism is evident in the newborn period because of parathyroid gland agenesis.

Autosomal dominant hypoparathyroidism (ADH) type 1 is due to point mutations in the *CaSR* gene, which render the protein constitutively active. This property enables the receptor to mediate suppression of PTH secretion at normal and even subnormal serum calcium levels. Many mutations have been described; affected individuals typically have mild hypoparathyroidism (mildly reduced serum $[Ca^{2+}]$ and PTH levels). These patients also demonstrate marked hypercalciuria due to mutant CaSRs in their kidneys. The set-point for calcium-induced suppression of PTH secretion in these patients is shifted to the left, as is the effect of serum $[Ca^{2+}]$ on renal calcium excretion. ADH type 2 is due to gain-of-function mutations in gene encoding G-alpha 11, which couples to the CaSR leading to enhanced suppression of PTH secretion at even low serum calcium levels. Thus, ADH types 1 and 2 are the mirror images of FHH types 1 and 2. Therapy is often not necessary and risks precipitating even greater degrees of hypercalciuria, nephrocalcinosis, and renal stones.

Other Causes of Hypoparathyroidism

Neonatal hypoparathyroidism can be part of the **DiGeorge syndrome** (dysmorphic facies, cardiac defects, immune deficiency, and hypoparathyroidism) due to a microdeletion (or other genetic abnormalities) on chromosome 22q11.2; the **HDR syndrome** (hypoparathyroidism, sensorineural deafness, and renal anomalies) due to mutations in or deletion of an allele of the *GATA3* transcription factor; and other rare conditions. Transfusion-dependent individuals with thalassemia or red cell aplasia who survive into the third decade of life are susceptible to hypoparathyroidism as the result of iron deposition in the parathyroid glands. Copper deposition can cause hypoparathyroidism in Wilson disease. Infiltration with metastatic carcinoma is a very rare cause of hypoparathyroidism.

Severe magnesium depletion temporarily paralyzes the parathyroid glands, preventing secretion of PTH. Magnesium depletion also blunts the actions of PTH on target organs (kidney and bone) to counteract the hypocalcemia. This is seen with magnesium losses due to gastrointestinal and renal disorders and chronic alcoholism. The syndrome responds immediately to infusion of magnesium. As discussed earlier in the section on regulation of PTH secretion, magnesium is required for effective stimulus-secretion coupling in the parathyroids. Several inherited disorders of renal tubular dysfunction lead to the loss of magnesium and can cause hypomagnesemia and hypocalcemia.

2. PSEUDOHYPOPARATHYROIDISM

PHP is a genetic disorder of target-organ unresponsiveness to PTH. Biochemically, it mimics hormone-deficient forms of hypoparathyroidism, with hypocalcemia and hyperphosphatemia, but the PTH level is elevated, and there is a markedly blunted response to the administration of PTH (see Diagnosis discussed later).

Clinical Features

Two distinct forms of PHP are recognized. PHP type IB is a disorder of isolated resistance to PTH, which presents with the biochemical features of hypocalcemia, hyperphosphatemia, and secondary hyperparathyroidism. PHP type IA has, in addition to these biochemical features, a characteristic somatic phenotype known as **Albright hereditary osteodystrophy (AHO)**. This consists of short stature, round face, short neck, obesity, brachydactyly (short digits), shortened metatarsals, subcutaneous ossifications, and often reduced intelligence. Because of shortening of the metacarpal bones—most often the fourth and fifth metacarpals—affected digits have a dimple, instead of a knuckle, when a fist is made (Figure 8–19). Primary hypothyroidism is frequently seen. Less commonly, these patients have abnormalities of reproductive function—oligomenorrhea in females and infertility in males due to primary hypogonadism. Interestingly, certain individuals in families with PHP inherit the somatic phenotype of AHO without any disorder of calcium metabolism; this state, which mimics PHP, is called **pseudo-PHP** or **PPHP**.

Pathophysiology

PHP type IA is caused by the loss of function of one allele (haploinsufficiency) of the gene encoding the stimulatory G protein alpha subunit, (G_s *alpha* or *GNAS*). This abnormality is predicted to produce only 50% of the normal levels of the alpha subunit of the heterotrimeric G_s, which couples the PTH receptor to adenylyl cyclase. Patients with PHP type IA have a markedly blunted response of urinary cAMP to administration of PTH. Because G_s also couples many other receptors to adenylyl cyclase, the expected result of this mutation would be a generalized disorder of hormonal unresponsiveness. The presence of primary hypothyroidism and primary hypogonadism in these patients indicates that resistance to TSH, LH, and FSH occurs fairly commonly. Responsiveness to other hormones (eg, ACTH, glucagon) is fairly normal. Thus, a 50% loss of the G_s alpha protein produces resistance to some hormones, but not others. *GNAS* is also mutated in individuals with PPHP, who have AHO but normal responsiveness to PTH. Thus, a mutation in *GNAS* invariably produces AHO but only sometimes produces resistance to PTH, suggesting that the occurrence of a metabolic phenotype is determined by other factors described later (Table 8–8).

In PHP type IB, there is resistance to PTH but no somatic phenotype (ie, no AHO). The disorder is linked to the *GNAS* locus but is not due to mutations in the coding region of *GNAS*. Loss of parent-specific imprinting patterns underlie PHP IB. Epigenetic defects in *GNAS* cause the differentially methylated region at exon A/B to lose its imprinting function. Most cases demonstrate a maternally derived 3-kb deletion of DNA sequences

located more than 200 kb centromeric of the *GNAS* locus at the *STX16* locus. Other deletions remove this entire differentially methylated region—a key regulator of the levels of *GNAS* transcription. Transcription directed by this (unmethylated) promoter does not produce appropriate levels of G$_s$ alpha protein in the renal cortex where this biallelic promoter activity is important. Thus, abnormal methylation of *GNAS* regulatory sequences plays a key role in the pathogenesis of PHP IB.

Progressive osseous heteroplasia (POH) is another rare disorder that involves the *GNAS* locus (see Table 8–8). Ectopic bone formation occurs in this disorder, similar but to a more severe extent than in PHP IA. POH begins in early childhood with ectopic bone forming in the dermis, muscles, and connective tissues. Features can include AHO (short stature, brachydactyly), but there are no calcium or PTH abnormalities. POH is considered part of the spectrum of *GNAS* disorders.

Genetics

PHP type IA is inherited as an autosomal dominant trait. Individuals who have acquired the trait from their fathers almost always present with PPHP and lack hormone resistance. When the mutant allele is derived from the mother, PHP with hormone resistance is always present. This pattern of inheritance is due to genomic imprinting of the *GNAS* locus. In the kidney cortex, the maternal allele is preferentially expressed, and the paternal allele is silenced. Thus, if the mutant *GNAS* allele is maternally derived, the resulting offspring will have PHP; if the mutant *GNAS* allele is paternally derived (and therefore silenced), the resulting offspring will have PPHP. Tissue-specific imprinting of the *GNAS* gene, therefore, determines the expression of hormone resistance in the kidney and thyroid. The expression of AHO does not depend on imprinting mechanisms and occurs in PHP type IA and PPHP.

Most cases of PHP IB are sporadic. The few inherited cases that haven characterized are the result of deletions of maternally-derived cis-acting control elements in the *GNAS* locus. Additionally, there are cases of uniparental isodisomy described. POH, in contrast to PHP, is due to paternal loss of function mutations in *GNAS*.

Diagnosis

Several disorders present with hypocalcemia and secondary hyperparathyroidism (eg, vitamin D deficiency), but when these features occur together with hyperphosphatemia or AHO, this suggests the diagnosis of PHP. To confirm that resistance to PTH is present, the patient can be challenged with PTH (the Ellsworth-Howard test). For this purpose, synthetic human PTH(1-34) (teriparatide acetate, 3 IU/kg body weight) is infused intravenously over 10 minutes during a water diuresis, and urine is collected during the hour preceding the infusion, during the half-hour following the infusion, 30 to 60 minutes after the infusion, and 1 to 2 hours after the infusion and assayed for cAMP and creatinine. Data are expressed as nanomoles of cAMP per liter of glomerular filtrate, based on creatinine measurements. Normally, there is an increase in urinary cAMP of more than 300 nmol/L glomerular filtrate after administration of PTH. The use of the urinary phosphate response as a gauge of PTH responsiveness is much less reliable. For practical purposes, hypocalcemia, hyperphosphatemia, elevated PTH levels, and normal levels of vitamin D metabolites (with or without AHO) confirm the presence of resistance to PTH.

3. VITAMIN D DEFICIENCY

Pathogenesis

Vitamin D deficiency results from one or more factors: inadequate sunlight exposure, inadequate nutrition, or malabsorption. In addition, drugs that activate the catabolism of vitamin D and its metabolites, such as phenytoin and phenobarbital, can precipitate vitamin D deficiency in subjects with marginal vitamin D status. Although the human skin is capable of producing sufficient amounts of vitamin D if exposed to sunlight of adequate intensity, institutionalized and home-bound patients frequently do not get adequate exposure. Furthermore, the fear of skin cancer has led many to avoid sunlight exposure or to apply protective agents that block the ultraviolet portion of sunlight from reaching the lower reaches of the epidermis where most of the vitamin D is produced. Heavily pigmented and elderly individuals have less efficient production of vitamin D for a given exposure to ultraviolet irradiation. Serum levels of 25(OH)D are used to indicate vitamin D status. Although there is no consensus on what level of 25(OH)D constitutes sufficiency, 30 ng/mL has become the preferred target in North America by many experts. Recent recommendations from an expert panel formed by the Institute of Medicine, however, concluded that 20 ng/mL was "sufficient." Using the level of 30 ng/mL as a standard, a large portion of the population is vitamin D-insufficient. A recent NHANES survey found that in the population over age 60, 67% of Caucasians, 82% of Hispanics, and 88% of African Americans had 25(OH)D levels below 30 ng/mL. Studies of hospitalized patients or those in nursing homes show almost universal vitamin D insufficiency, if not frank deficiency. The intensity of sunlight is an important factor that limits effective vitamin D production as a function of season (summer > winter) and latitude (less intense the higher the latitude). The supplementation of milk has reduced the incidence of vitamin D

deficiency in the United States, but most countries do not follow this practice. Even in the United States, severe vitamin D deficiency and rickets may occur in children of vegetarian mothers who avoid milk products (and presumably have reduced vitamin D stores) and in children who are not weaned to vitamin D-supplemented milk by age 2. Breast milk contains little vitamin D, although vitamin D content can be increased by supplementing the mother. Adults who avoid milk as well as sunlight are likewise at risk. Individuals with a variety of small bowel, pancreatic, and biliary tract disease and those after partial gastrectomy or intestinal bypass surgery have reduced capacity to absorb the vitamin D from the diet.

Clinical Features

The clinical features of individuals with severe vitamin D deficiency will be discussed more thoroughly in the section on "Osteomalacia and Rickets." Severe vitamin D deficiency should be suspected in individuals complaining of lethargy, proximal muscle weakness, and bone pain who have frankly low or low normal serum calcium and phosphate and low urine calcium on routine biochemical evaluation. A low serum 25(OH)D level is diagnostic in this setting. $1,25(OH)_2D$ levels are often normal and reflect the increased 1-hydroxylase activity in these subjects that is responding appropriately to the increased PTH levels as well as the low serum calcium and phosphate levels. However, there is increasing awareness that less severe degrees of vitamin D deficiency may not present with obvious musculoskeletal signs and symptoms. These individuals may be more susceptible to conditions such as hyperparathyroidism, osteoporosis, increased risk of falls and fractures, but also increased infections, hypertension, increased cardiovascular disease, diabetes mellitus, and various malignancies. Convincing data from large-scale randomized placebo controlled clinical trials demonstrating cause and effect for vitamin D deficiency and many of these disorders are lacking, although animal studies and a large body of epidemiologic evidence and case control studies point in this direction.

Treatment

The goal in treating severe vitamin D deficiency manifesting as rickets or osteomalacia is to normalize the clinical, biochemical, and radiologic abnormalities without producing hypercalcemia, hyperphosphatemia, hypercalciuria, nephrolithiasis, or ectopic calcification. To realize this goal, patients must be followed carefully. As the bone lesions heal or the underlying disease improves, the dosage of vitamin D, calcium, or phosphate needs to be adjusted to avoid such complications. With the appreciation that most individuals have a less severe form of vitamin D deficiency and do not have obvious signs or symptoms associated with rickets or osteomalacia, the goal of treatment is to achieve a level of 25(OH)D that existing data indicate will reduce the predisposition of such individuals to the numerous diseases associated with vitamin D deficiency. Correction of vitamin D deficiency can usually be achieved by the weekly administration of 50,000 IU ergocalciferol for 6 to 8 weeks followed by replacement doses of 800 to 2000 IU/d based on maintenance of adequate serum 25(OH)D levels. Patients with malabsorption including patients

after bariatric surgery may require larger amounts of vitamin D. 25(OH)D (50-100 μg/d) is better absorbed than vitamin D and may be used, if malabsorption of vitamin D is a limiting factor, but this metabolite of vitamin D is not readily available in the United States. Calcitriol $[1,25(OH)_2D]$ and its analogs are not appropriate therapy for patients with vitamin D deficiency because of the likely requirement for vitamin D metabolites other than $1,25(OH)_2D$ and the advantage of providing adequate substrate [25(OH)D] for tissues capable of producing their own $1,25(OH)_2D$ as the need arises (eg, as in the immune response). The exception to this rule is in patients with renal failure who are incapable of producing adequate $1,25(OH)_2D$. Vitamin D therapy should be combined with calcium based on current recommendations for daily calcium intake (see the section "Nonpharmacologic Aspects of Osteoporosis Management" and Table 8–12). Care must be taken in managing patients with vitamin D deficiency who also have elevated PTH levels, because longstanding vitamin D deficiency may produce a degree of autonomy in the parathyroid glands such that rapid replacement with calcium and vitamin D could result in hypercalcemia or hypercalciuria. A listing of available vitamin D metabolites and analogs with their main indications for clinical use is presented in Table 8–2.

4. PSEUDOVITAMIN D DEFICIENCY

Pseudovitamin D deficiency is a rare autosomal recessive disease in which rickets is accompanied by low levels of $1,25(OH)_2D$ but normal levels of 25(OH)D. The disease is due to mutations in the *25(OH)D 1-hydroxylase* gene (*CYP27B1*) that render it nonfunctional. Both alleles need to be defective in order for the disease to be manifest. Although affected patients do not respond to doses of vitamin D that are effective in subjects with vitamin D deficiency, they can respond to pharmacologic doses of vitamin D and to physiologic doses of calcitriol, which is the preferred treatment.

5. HEREDITARY VITAMIN D–RESISTANT RICKETS

Hereditary vitamin D–resistant rickets is a rare autosomal recessive disease that presents in childhood with rickets similar to that seen in patients with vitamin D deficiency. Many of these patients also have alopecia, which is not characteristic of vitamin D deficiency or pseudovitamin D deficiency. The biochemical changes are similar to those reported in subjects with vitamin D deficiency except that the $1,25(OH)_2D$ levels are generally very high. The disease is caused by inactivating mutations in the *VDR*. The location of the mutation can affect the severity of the disease. In particular, mutations in the DNA-binding domain (exons 2, 3) that prevent DNA binding and mutations in the ligand-binding domain (exons 5-7) that prevent $1,25(OH)_2D$ binding lead to a more severe phenotype. The latter mutations may alter but not inhibit DNA/ligand binding. These patients are treated with large doses of calcitriol and dietary calcium and may show partial or complete remission as they grow older. An animal

model of this disease (inactivation or knockout of both *VDR* alleles) demonstrates that the bone disease can be corrected with high dietary intake of calcium and phosphate, although the alopecia is not altered. This disease points to a role for the VDR in epidermis and hair development that is independent of its activity in the intestine and bone.

6. OTHER HYPOCALCEMIC DISORDERS

Hypoalbuminemia produces a low total serum $[Ca^{2+}]$ because of a reduction in the bound fraction of calcium, but the ionized $[Ca^{2+}]$ is normal. The ionized $[Ca^{2+}]$ can be determined directly, or the effect of hypoalbuminemia can be roughly corrected for by using the following formula:

$$Corrected\ serum\ calcium = Measured\ serum\ calcium + (0.8)$$
$$(4 - Measured\ serum\ albumin)$$

Thus, in a patient with a serum $[Ca^{2+}]$ of 7.8 mg/dL and a serum albumin of 2 g/dL, the corrected serum $[Ca^{2+}]$ is 7.8 + (0.8)(4 − 2) = 9.4 mg/dL.

Several disorders produce acute hypocalcemia even if homeostatic mechanisms are intact, simply because they overwhelm these mechanisms. Acute hyperphosphatemia resulting from rhabdomyolysis or tumor lysis, often in the setting of renal insufficiency, may produce severe symptomatic hypocalcemia. Transfusion of large volumes of citrated blood causes acute hypocalcemia by complexation of calcium as calcium citrate. In this instance, total calcium may be normal, but the ionized fraction is reduced. In acute pancreatitis, hypocalcemia is an ominous prognostic sign. The mechanism of hypocalcemia is sequestration of calcium by saponification with fatty acids, which are produced in the retroperitoneum by the action of pancreatic lipases. Skeletal mineralization, when very rapid, can cause hypocalcemia. This is seen in the **hungry bone syndrome**, which was discussed earlier in the section on surgical hypoparathyroidism, and occasionally with widespread osteoblastic metastases from prostatic carcinoma.

TREATMENT OF HYPOCALCEMIA

Acute Hypocalcemia

Patients with tetany should receive intravenous calcium preferably as calcium gluconate (90 mg calcium/10 mL) or calcium gluceptate (90 mg calcium/10 mL) over 10 to 20 minutes. Approximately 200 mg of elemental calcium can be given over 20 to 40 minutes by slow intravenous infusion with constant electrocardiographic monitoring. The patient must be observed for stridor and the airway secured if necessary. Oral calcium and a rapidly acting preparation of vitamin D (eg, calcitriol) should be started. If necessary, calcium can be infused in doses of 400 to 1000 mg/24 h until oral therapy has taken effect. Intravenous calcium is irritating to the veins and is best infused into a large vein or through a central venous catheter.

Chronic Hypocalcemia

The objective of chronic therapy is to keep the patient free of symptoms and to maintain a serum $[Ca^{2+}]$ of approximately 8.5 to 9.0 mg/dL. With lower serum $[Ca^{2+}]$, the patient may not only experience symptoms but may be predisposed over time to cataract formation if the phosphate level is also high. With serum calcium concentrations in the upper normal range, there may be marked hypercalciuria, which occurs because the hypocalciuric effect of PTH has been lost. This may predispose to nephrolithiasis, nephrocalcinosis, and chronic renal disease. In addition, the patient with borderline elevated calcium is at increased risk of overshooting the therapeutic goal and may develop symptomatic hypercalcemia.

The mainstays of treatment are calcium and a form of vitamin D. Oral calcium can be given in a dose of 1.5 to 3 g of elemental calcium or more per day. These large doses of calcium reduce the doses of vitamin D that are needed and allow for rapid normalization of serum calcium if vitamin D intoxication subsequently occurs. Numerous preparations of calcium are available. A short-acting preparation of vitamin D (calcitriol) and the very long-acting preparations such as vitamin D_2 (ergocalciferol) are available and can be used (see Table 8–2). Although regimens that use ergocalciferol are economical, they have the disadvantage of the long half-life of vitamin D_2 if vitamin D intoxication occurs. Additionally, high doses of vitamin D_2 are needed to treat hypoparathyroidism, if that is the agent is to be used. In PTH deficiency states, the effects of endogenous PTH on renal 1-alpha hydroxylase activity are missing, and there is little conversion of $25(OH)D$ to $1,25(OH)_2D$. Caution must be exercised in the introduction of other drugs that influence calcium metabolism. For example, thiazide diuretics have a hypocalciuric effect. By reducing urinary calcium excretion in treated patients, whose other adaptive mechanisms such as the modulation of PTH secretion by calcium, are nonoperative and who are thus absolutely dependent on renal excretion of calcium to maintain the serum calcium level, thiazides may produce significant hypercalcemia. In a similar way, intercurrent illnesses that compromise renal function (and therefore calcium excretion) may produce dangerous hypercalcemia in the patient who is maintained on large doses of vitamin D. Short-acting preparations of vitamin D (eg, calcitriol or $1,25(OH)_2D$ and 1-alpha calcidiol) are less prone to some of these effects but may require more frequent titration and are more expensive than vitamin D_2.

BONE ANATOMY AND REMODELING

FUNCTIONS OF BONE

Bone has four major functions:

1. It provides rigid support to extremities and body cavities containing vital organs. In diseases in which the skeleton is weakened or defective, erect posture may be impossible and vital

organ function may be compromised. An example is the cardiopulmonary dysfunction that occurs in patients with severe kyphosis due to vertebral collapse.

2. Bones are crucial to locomotion in that they provide efficient levers and sites of attachment for muscles. With bony deformity, these levers become defective, and severe abnormalities of gait develop.

3. Bone provides a large reservoir of ions, such as calcium, phosphate, magnesium, and sodium that are critical for life and can be mobilized when the external environment fails to provide them.

4. Bone houses the hematopoietic elements. There is increasing evidence of a trophic relationship between the stromal cells in bone and the hematopoietic elements.

STRUCTURE OF BONE

The material properties of normal bone strike an ideal balance between rigidity and elasticity. Bone is rigid enough to provide structural stability and resist applied forces but not overly mineralized and brittle, which would result in an increased tendency to fracture. Bone must also be light enough to be moved by muscle contractions. Cortical bone, composed of densely packed layers of mineralized collagen, provides rigidity and is the major component of tubular bones (Figure 8–20). Trabecular (cancellous) bone is spongy in cross-section, provides strength and elasticity, and constitutes the major portion of the axial skeleton. Disorders in which cortical bone is defective or reduced in mass lead to
FIGURE 8–20 Diagram showing features of the microstructure of mature bone seen in both transverse (top) and longitudinal section. Areas of cortical (compact) and trabecular (cancellous) bone are included. (Reproduced with permission from Standring S. *Gray's Anatomy*. 40th ed. Churchill Livingstone/Elsevier; 2008.)

fractures of the long bones. Disorders in which trabecular bone is defective or scanty, in contrast, lead preferentially to vertebral fractures. Fractures of long bones may also occur because normal trabecular bone reinforcement is lost.

Two-thirds of the weight of bone is due to mineral; the remainder is due to water and type I collagen. Minor organic components such as proteoglycans, lipids, acidic proteins containing gamma-carboxyglutamic acid, osteonectin, osteopontin, and growth factors comprise the remainder.

Bone Mineral

The mineral of bone is present in two forms. The major form consists of hydroxyapatite in crystals of varying maturity. The remainder is amorphous calcium phosphate, which lacks a coherent x-ray diffraction pattern, has a lower calcium-to-phosphate ratio than pure hydroxyapatite, occurs in regions of active bone formation, and is present in larger quantities in young bone.

Bone Cells

Bone is composed of three types of cells: the osteoblast, the osteocyte, and the osteoclast.

A. Osteoblast   The osteoblast is the principal bone-forming cell. It arises from a pool of mesenchymal stem cells in the bone marrow, which as they differentiate, acquire a set of characteristics, including expression of PTH and vitamin D receptors; surface expression of the ectoenzyme alkaline phosphatase; and expression of bone matrix protein genes—type I collagen, osteocalcin, osteopontin, and others. Differentiated osteoblasts are directed to the bone surface, where they line regions of new bone formation, laying down bone matrix (osteoid) in orderly lamellae and inducing its mineralization (Figure 8–21). In the

FIGURE 8–21   The remodeling cycle. **A.** Resting trabecular surface. **B.** Multinucleated osteoclasts dig a cavity of approximately 20 microns. **C.** Completion of resorption to 60 microns by mononuclear phagocytes. **D.** Recruitment of osteoblast precursors to the base of the resorption cavity. **E.** Secretion of new matrix (gray shading) by osteoblasts. **F.** Continued secretion of matrix, with initiation of calcification (black areas). **G.** Completion of mineralization of new matrix. Bone has returned to quiescent state, but a small deficit in bone mass persists.

mineralization process, hydroxyapatite crystals are deposited on the collagen layers to produce lamellar bone. Mineralization requires an adequate supply of extracellular calcium and phosphate as well as alkaline phosphatase, which is secreted in large amounts by active osteoblasts. The fate of senescent osteoblasts is not well defined. Some probably become flattened, inactive lining cells on trabecular bone surfaces, some are buried in cortical bone as osteocytes, and others undergo apoptosis.

B. Osteocyte   Osteoblasts that remain within cortical bone during the remodeling process become osteocytes. Protein synthetic activity decreases markedly, and the cells develop multiple processes (canaliculi) that reach out through lacunae in bone tissue to communicate with nutrient capillaries, with processes of other osteocytes within a unit of bone (osteon), and also with the cell bodies of surface osteoblasts (see Figure 8–20). The physiologic functions of osteocytes are varied. They are believed to (1) act as a cellular syncytium that permits the translocation of mineral in and out of regions of bone removed from surfaces; (2) serve as the sensors of mechanical loading by providing key signals that trigger bone modeling and remodeling; and (3) produce key factors and hormones that modulate functions of distant tissues (eg, FGF23 affecting phosphate excretion and $1,25(OH)_2D$ metabolism).

C. Osteoclast   The osteoclast is a multinucleated giant cell that is specialized for resorption of bone. Osteoclasts are terminally differentiated cells that arise from hematopoietic precursors in the monocyte lineage and do not divide. Osteoblasts stimulate both osteoclast formation and activation via the cell surface molecule RANKL and soluble RANKL released into the bone microenvironment. RANKL stimulates its cognate ligand RANK on the surface of osteoclast precursors and mature osteoclasts (Figure 8–22). Osteoblasts also elaborate macrophage colony stimulating factor-1 (M-CSF), which is required for the full effects of RANKL on osteoclastogenesis. In addition, osteoblasts and other cells produce a decoy receptor, osteoprotegerin (OPG), which binds to RANKL and blocks its actions. PTH and $1,25(OH)_2D$ both increase RANKL production by osteoblasts, as do many cytokines including IL-1, IL-6, and IL-11. TNF-alpha potentiates the ability of RANKL to stimulate osteoclastogenesis, whereas IFN-gamma blocks this process by direct effects on the osteoclast.

To resorb bone, the motile osteoclast alights on a bone surface and seals off an area by forming an adhesive ring. Having isolated an area of bone surface, the osteoclast develops above the surface an elaborately invaginated plasma membrane structure called the **ruffled border** (Figure 8–23). The ruffled border is a distinctive organelle, but it acts essentially as a huge lysosome that dissolves bone mineral by secreting acid onto the isolated bone surface and simultaneously breaks down bone matrix by secretion of proteases, in particular cathepsin K. The collagen breakdown products from bone resorption can be assayed in serum and urine as measures of bone resorption rates (*N*- and *C*-telopeptides). Bone resorption can be controlled in several ways: by regulating the formation of

FIGURE 8–22 Regulation of osteoclast formation and activation by the osteoblast. The osteoblast stimulates osteoclast formation and activation via the interaction of RANKL on the osteoblast with RANK on the osteoclast. M-CSF secreted by the osteoblast enhances the process via its receptor on the osteoclast C-FMS, whereas OPG, also secreted by the osteoblast, blocks the process by blocking RANKL. RANKL expression is stimulated by 1,25(OH)$_2$D and PTHrP/PTH as well as by the cytokines IL-1, IL-6, and IL-11.

osteoclasts via changes in cell numbers, by regulating the activity of mature osteoclasts, and by altering the function of key enzymes that degrade the bone matrix. The mature osteoclast has receptors for CT but does not appear to have PTH or vitamin D receptors.

BONE MODELING AND REMODELING

Bone remodeling is a continuous process of breakdown and renewal that occurs throughout life. During childhood and adolescence, remodeling proceeds at a vigorous rate but is quantitatively overwhelmed by the concomitant occurrence of bone modeling and linear growth. Once peak bone mass has been established, remodeling supervenes as the common mechanism by which bone mass is modified for the remainder of a person's life. Each remodeling event is carried out by individual "bone remodeling units" on bone surfaces throughout the skeleton (see Figure 8–21). Normally, about 90% of these surfaces lie dormant, covered by a thin layer of lining cells. Following physical or biochemical signals, precursor cells from the bone marrow migrate to specific loci on the bone surface, where they fuse into multinucleated bone-resorbing cells known as osteoclasts that then excavate a resorption cavity into the bone.

FIGURE 8–23 Osteoclast-mediated bone resorption. The osteoclast attaches to the bone surface via integrin-mediated binding to bone matrix bone proteins. When enough integrin binding has occurred, the osteoclast is anchored and a sealed space is formed. The repeatedly folded plasma membrane creates a ruffled border. Secreted into the sealed space are acid and enzymes forming an extracellular lysosome. (Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism*. 3rd ed. New York: McGraw-Hill Education; 1995.)

FIGURE 8–24 Schematic representation of the four principal stages involved in the formation of a new basic structural unit in cortical bone. (Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism.* 3rd ed. New York: McGraw-Hill Education; 1995.)

Cortical bone is remodeled from within by cutting cones, groups of osteoclasts that cut tunnels through the compact bone (Figure 8–24). They are followed by trailing osteoblasts that line the tunnels with a cylinder of new bone, progressively narrowing the tunnels until all that remains are the tiny haversian canals by which the cells left behind as resident osteocytes are fed. The packet of new bone formed by a single cutting cone is called an osteon (see Figure 8–20).

By contrast, trabecular resorption creates scalloped areas of the bone surface called Howship lacunae. Two to three months after initiation, the resorption phase reaches completion, having created a cavity about 60 μm deep. This is accompanied by ingress from marrow stroma into the base of the resorption cavity of precursors for bone-forming osteoblasts. These cells develop an osteoblastic phenotype, expressing characteristic bone-specific proteins such as alkaline phosphatase, osteopontin, and osteocalcin, and begin to replace the resorbed bone by elaborating new bone matrix. Once the newly formed osteoid reaches a thickness of about 20 μm, mineralization begins. Completion of a full remodeling cycle normally takes about 6 months (see Figure 8–21).

Bone remodeling does not absolutely require systemic hormones except to maintain intestinal absorption of minerals by $1,25(OH)_2D$ and thus ensure an adequate supply of calcium and phosphate. For example, bone is relatively normal, aside from being in a state of low turnover and being dense, in patients with hypoparathyroidism. However, systemic hormones use the "bone pool" as a source of minerals for regulation of extracellular calcium homeostasis. When they do, the coupling mechanism ensures that bone is replenished. For example, when bone resorption is activated by PTH to provide calcium to correct hypocalcemia, bone formation also increases, tending to replenish lost bone. Although

the role of the osteoblast in regulating osteoclast activity is reasonably well understood, the mechanism by which osteoblasts are recruited to sites of bone resorption is not. One possibility is that bone resorption releases IGF-1 from the bone matrix, and IGF-1 then stimulates osteoblast proliferation and differentiation. However, it is also becoming clear that the osteoclast itself can regulate osteoblast differentiation through bidirectional signaling molecules of the ephrin/Eph family. Transforming growth factor (TGF) beta is also released from the bone matrix with resorption, which also plays a role in stimulating formative responses.

If the replacement of resorbed bone matched the amount that was removed, remodeling would lead to no net change in bone mass. However, small deficits in bone mass persist on completion of each cycle, reflecting inefficiency in remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary insufficiency, hormones, and drugs affect bone balance. A change in whole body remodeling rate can be brought about through distinct perturbations in remodeling dynamics. Changes in the hormonal milieu often increase the activation of remodeling units. Examples include hyperthyroidism, hyperparathyroidism, and hypervitaminosis D. Other factors may impair osteoblastic functional adequacy, such as high doses of glucocorticoids or ethanol. Yet other perturbations, such as estrogen or androgen deficiency, may augment osteoclastic resorptive capacity. At any given time, a transient deficit in bone exists called the **remodeling space** representing sites of bone resorption that have not yet filled in. In response to any stimulus that alters the birth rate of new remodeling units, the remodeling space either increases or decreases accordingly until a new steady state is established, and this adjustment is seen as an increase or decrease in bone mass.

OSTEOPOROSIS

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. The term **primary osteoporosis** denotes reduced bone mass and fractures in postmenopausal women (postmenopausal osteoporosis) or in older men and women due to age-related factors. The term **secondary osteoporosis** refers to bone loss resulting from specific clinical disorders, such as thyrotoxicosis, glucocorticoid excess and many others (Table 8–9). There is overlap in these designations; for example, many postmenopausal women with low bone mass have vitamin D insufficiency or deficiency which could be considered a secondary cause of osteoporosis.

Osteoporotic fractures are a major public health problem for older women and men in Western society. Half the men and women over age 55 have low bone mass (osteopenia) or osteoporosis, placing them at increased risk of fracture. At any age, women experience twice as many osteoporosis-related fractures as men, reflecting gender-related differences in skeletal properties as well as the almost universal loss of bone at menopause. However,

History of falls
Low bone mineral density

the number of osteoporotic fractures in older men is not trivial (Figure 8–25). One of six Caucasian women suffers a hip fracture; mortality after hip fracture is as high as 20% in the first year. One-third of hip fractures occur in men and have been associated with an even higher mortality rate than in women. Billions of dollars are spent annually for acute hospital care of hip fracture alone. The consequences of vertebral deformity are also significant and include chronic pain, inability to conduct daily activities, depression, increased mortality, and high risk of additional vertebral fractures.

Typically, fractures attributed to bone fragility are those due to trauma equal to or less than a fall from a standing position.
FIGURE 8–25 Incidence rates for the three common osteoporotic fractures (Colles, hip, and vertebral) in men and women, plotted as a function of age at the time of the fracture. (Reproduced with permission from Cooper C, Melton LJ. Epidemiology of osteoporosis. *Trends Endocrinol Metab.* 1992 Aug;3(6):224-229.)

Common sites of fragility-related fractures include the vertebral bodies, distal forearm, and proximal femur, but because the skeletons of patients with osteoporosis are diffusely fragile, other sites, such as ribs and long bones, also fracture with high frequency. Vertebral compression fractures are the most common fragility-related fractures. Pain sufficient to require medical attention occurs in approximately one-third of vertebral fractures, the majority being detected only when height loss or spinal deformity (kyphosis) occurs. However, even asymptomatic vertebral fractures confer an increased risk of future vertebral fractures and mortality. Thus, incidentally detected vertebral fractures have the same significance as a clinical vertebral fracture in this regard. Furthermore, even fractures that appear to be due to trauma portend an increased future fracture risk. Both skeletal and extraskeletal factors determine fracture risk (Table 8–10).

Gain, Maintenance, and Loss of Bone

The amount of bone mineral present at any time in adult life represents that which has been gained at skeletal maturity (peak bone mass) minus that which has been subsequently lost. Bone acquisition is completed in the late teenage years and early twenties in girls and by the second decade in boys. Heredity accounts for most of the variance in bone acquisition. African American adolescent girls have greater calcium retention on a fixed calcium intake compared to Caucasian adolescent girls, potentially explaining at least part of the racial differences in bone mass. Specific genes implicated in bone acquisition include those affecting body size, hormone responsiveness, and bone-specific proteins such as type 1 collagen and TGF beta.

The **Wnt pathway** plays a central role in determining bone mass. The low density lipoprotein (LDL) receptor-like protein 5/6 (LRP5/6) along with the frizzled protein serves as coreceptor for members of the Wnt family of ligands. Activation of Wnt and its downstream signaling pathways mediates increased osteoblastic activity (gene expression, cell proliferation and differentiation). Mutations that render LRP5 constitutively active are associated with high bone mass, and autosomal recessive inactivating mutations in *LRP5* play a causative role in the

osteoporosis-pseudoglioma syndrome. These mutations lead to accelerated bone loss and fractures as well as blindness. These two disorders of bone mass have firmly established Wnt, LRP5, and frizzled as essential molecules in osteoblast-mediated bone formation.

Other factors contributing to the acquisition of peak bone mass include circulating gonadal steroids, physical activity, and nutrient intake. In adolescents, calcium retention is maximal at a calcium intake of 1300 mg/d; this is the current recommended intake for individuals aged 9 to 18 years. Adolescence is a critical time for the skeleton; bone gained during adolescence accounts for about 60% of final adult bone mass. Assuming adequate exposure to key nutrients, physical activity, and reproductive hormones, adolescent growth supports acquisition of the maximum bone mass permitted by the genetic endowment. Estradiol plays a decisive role in the initiation of adolescent growth and bone acquisition. Rare examples have been reported of young men bearing mutations in the estradiol receptor or in aromatase, the enzyme that converts androgen to estrogen. Although these men had normal or increased circulating concentrations of testosterone, estradiol was either absent or totally ineffective. In all cases, severe deficits in BMD were observed, and these patients had not undergone the anticipated acceleration in linear growth at the time of puberty. In the patients with aromatase deficiency, substantial gains in bone were observed shortly after initiating estrogen therapy.

Adolescent bone acquisition falters in the face of inadequacies in diet, physical activity, or reproductive function, resulting in a lower peak bone mass and less reserve to accommodate future losses. Recent trends in habitual physical activity and calcium intake for North American teenagers, particularly girls, offer little encouragement in this regard. A list of representative conditions

TABLE 8–11 Examples of disorders associated with reduced peak bone mass.

Anorexia nervosa
Ankylosing spondylitis
Immobilization (bed rest, non-ambulatory status)
Cystic fibrosis
Delayed puberty
Exercise-associated amenorrhea
Galactosemia
Intestinal or renal disease
Marfan syndrome
Osteogenesis imperfecta

often associated with reduced peak bone mass acquisition is presented in Table 8–11.

Once peak bone mass is achieved, bone mass remains fairly stable until the late third or early fourth decades (Figure 8–26). Successful bone maintenance requires continued attention to the same factors that influenced bone acquisition: diet, physical activity, and sex hormone status. Maintenance of bone requires sufficiency in all areas, and one cannot compensate for a deficiency in another. For example, amenorrheic athletes lose bone despite frequent high-intensity physical activity and supplemental calcium intake. Successful bone maintenance is also jeopardized by known toxic exposures such as smoking, alcohol excess, and immobility as well as by systemic illnesses and many medications.

Bone Loss Associated with Estrogen Deficiency

Estrogen deprivation promotes bone remodeling by releasing constraints on the production and activity of cytokines, particularly
FIGURE 8–26 Mean bone mineral density by DXA in white males (upper curve) and females (lower curve) aged 5 to 85 years. (Data from Southard RN, et al. Bone mass in healthy children: measurement with quantitative DXA. *Radiology.* 1991;179:735; and from Kelly TL. Bone mineral reference databases for American men and women. *J Bone Miner Res.* 1990;5(Suppl 2):702.)

IL-6, which stimulates the proliferation of osteoclast precursors. Estradiol suppresses IL-6 secretion by marrow stromal osteoblastic cells. Treatment of mice with neutralizing IL-6 antibodies suppresses osteoclast production after oophorectomy, and *IL-6* gene knockout prevents bone loss in oophorectomized mice. Thus, a strong case implicates IL-6 as a critical molecule involved in estrogen action in bone. Subsidiary roles for IL-1 and IL-11 have also been described. As discussed earlier, the RANK-RANKL-OPG system acts as a bone regulatory system through which osteoblast signals stimulate the production of osteoclasts. With estrogen deficiency, OPG secretion is low, permitting a robust response of osteoclast precursors to RANKL, thereby increasing bone turnover.

With accelerated bone turnover, delivery of calcium from bone to the circulation increases, and the resultant subtle increase in plasma calcium concentration suppresses the secretion of PTH, thereby enhancing calciuria, suppressing renal production of $1,25(OH)_2D$, and reducing intestinal calcium absorption efficiency. At menopause, loss of endogenous estrogen promotes an increase in daily calcium loss from 20 mg to about 60 mg, reflecting a relative increase in bone resorption over formation activity. Although small, this magnitude of change in mineral balance accounts, after a decade, for about 13% of an original whole body calcium mass of 1000 g, equivalent to a standard deviation in BMD (see Figure 8–26), and leads to a two- to threefold increase in the risk of fracture. In the 5 years after menopause, women not on estrogen can lose as much as 5% to 8% of their bone mass. To accommodate menopausal changes in calcium economy by dietary means alone, a rise in daily calcium intake from 1000 mg to about 1500 mg would be necessary. Increased calcium intake can slow, but usually does not entirely prevent, the bone loss that occurs with menopause.

Bone Loss in Later Life

Progressive deficits in renal and intestinal function impair whole body calcium economy during normal human aging. These deficits include progressive inefficiency of vitamin D production by the skin as well as declining ability to convert 25(OH)D to $1,25(OH)_2D$ in the kidney. Consequently, intestinal calcium absorption becomes less efficient, leading to modest reductions in plasma ionized calcium activity and compensatory hypersecretion of PTH. PTH maintains blood calcium concentrations by activating new bone remodeling units, although as a result of its inherent inefficiency, increased bone remodeling leads to accelerated bone loss. Little can be done to counteract remodeling inefficiency, but the impact of these physiologic deficits can be minimized by suppressing the stimulus for PTH secretion by consuming adequate amounts of dietary calcium and vitamin D.

Diagnosis of Osteoporosis

The diagnosis of osteoporosis may be obvious in patients who have sustained fragility fractures (Figure 8–27), but noninvasive methods to estimate BMD are required to identify high-risk patients who have not yet sustained a fracture. Due to the significant consequences of fractures, diagnosis prior to fracture is essential. Several techniques have been developed for this purpose, but DXA offers the most precise measurements at multiple skeletal sites for the least amount of radiation exposure. Current
FIGURE 8–27   **A.** Magnified x-rays of thoracic vertebrae from a woman with osteoporosis. Note the relative prominence of vertical trabeculae and the absence of horizontal trabeculae. **B.** Lateral x-ray of the lumbar spine of a woman with postmenopausal osteoporosis. Note the increased density of the superior and inferior cortical margins of vertebrae, the marked demineralization of vertebral bodies, and the central compression of articular surfaces of vertebral bodies by intervertebral disks. (Used with permission from Dr. G. Gordan.)

guidelines recommend that all women 65 years and older be screened for osteoporosis using bone densitometry. The National Osteoporosis Foundation (NOF) Guideline recommends screening younger postmenopausal women with risk factors for fracture, while the United States Preventive Services Task Force recommends screening women under 65 years whose estimated fracture risk is at least that of a 65-year-old woman without additional risk factors. The NOF Guideline recommends screening men 70 years and older, and targeted screening of men ages 50 to 69 if there is a risk factor for fracture. There are no recommendations for routine screening of premenopausal women or men under 50 years, but younger men and women should have bone density testing if clinically indicated (eg, clinical evidence of bone fragility, chronic glucocorticoid therapy, and so forth).

BMD is a highly significant predictor of fracture risk. For each standard deviation BMD below the average BMD of individuals at the age of peak bone mass, fracture risk approximately doubles. Site-specific measurements best predict fracture risk at that site (ie, hip BMD best predicts hip fracture), but a measurement at any site predicts overall fracture risk. Based on data from Caucasian postmenopausal women and originally intended to be used as an epidemiologic tool, a World Health Organization (WHO) panel in 1994 offered an absolute standard for categorization of femoral neck BMD, and the International Society for Clinical Densitometry then extended the criterion to total hip and total posteroanterior lumbar spine BMD. By this standard, BMD values 2.5 or more SD below the average value for a person at the age of peak bone mass (a T-score of –2.5 or below) are categorized as **osteoporosis**. BMD values between –1.0 and –2.5 SD below the standard (T-score between –1 and –2.5) are categorized as low bone mass or **osteopenia**.

While not their original intended purpose, these T-score cut points became integrated into clinical practice and have been used to place individuals with low BMD into diagnostic categories. Problematically, there are no risk thresholds at these values; an individual with a T-score of –2.4 and an individual with a T-score of –2.5 have nearly identical fracture risk, but one is considered to have osteoporosis and one is not. Additionally, two individuals with the same T-score value can have very different fracture risk. A woman in her fifties with no personal or family history of fracture but a femoral neck T-score of –2.5 has a 10-year risk of fracture of less than 10%. However, an 80-year-old woman with the same femoral neck T-score of –2.5, whose mother had a hip fracture and who has a personal history of fracture, has a 10-year risk of fracture of more than 50%. It has long been recognized that the combination of risk factors for fracture and BMD can improve fracture risk prediction. The WHO Fracture Risk Assessment tool (http://www.shef.ac.uk/FRAX) formally estimates 10-year fracture risk from femoral neck bone density and clinical risk factors. The FRAX tool has greatly improved the clinician's ability to estimate fracture risk for an individual patient. The levels of risk at which treatment should be initiated are country-specific, but a cost-effectiveness analysis in the United States suggests that individuals with a 10-year probability of major osteoporotic fracture of 20% or higher or of hip fracture of 3% or higher should be considered for treatment. Limitations of this fracture prediction model include

that it only incorporates BMD by DXA at the femoral neck, many risk factors are not available in the model, and there is no way to incorporate the effect of prior treatment on fracture risk.

For premenopausal women and men under 50 years, assessment of BMD should be based on age-matched normative data (Z-scores). Although there are no formal guidelines and a paucity of long-term data, most experts consider a BMD more than two standard deviations below the age- and gender-matched normal reference population (a Z score of –2 or lower) to indicate low BMD in a young person. However, BMD in younger individuals must be interpreted in light of the clinical situation and other risk factors for fracture.

MANAGEMENT OF OSTEOPOROSIS

Nonpharmacologic Aspects of Osteoporosis Management

Much of the nonpharmacologic management of osteoporosis involves issues that are not specific for bone. These include exercise, fall prevention, and nutrition, and as appropriate, pain control, depression therapy, and assisting patients to organize activities of daily living.

A. Exercise   Minimal attention has been devoted to the role of exercise for patients with established osteoporosis. Patients and physicians often show reluctance to participate in exercise because of concerns for additional injury. However, activity avoidance aggravates bone loss and places the skeleton in even greater jeopardy, whereas improving muscle strength, particularly of the back extensor groups, constitutes a powerful means for reducing pain and increasing functional capacity. Even the most frail individuals can successfully implement exercise regimens with the assistance of a trained physical therapist. Exercise regimens that include a component of weight bearing and/or resistance exercise have been shown to increase BMD approximately 1% per year in randomized trials. If exercise is discontinued, these gains in BMD are lost.

Because the great majority of hip fractures are the immediate result of a fall, strategies aimed at reduction of falls are of critical importance. Muscle weakness is an important predictor of fall risk, and decreased muscle mass and strength are consequences of normal human aging. Resistance exercise (ie, weight training) promotes muscle strength even in very old men and women, and evidence suggests that increased lower extremity strength may reduce falls risk by improving postural stability. Thus, a widely disseminated program of leg-strengthening exercise could lower the risk of falling and reduce hip fracture incidence, even if no changes in BMD are achieved.

B. Other fall prevention measures   Proper footwear and installation of safety features around the home may minimize the risk of falling. Such features include bathroom safety rails, night lights, and rails and lighting for stairways. Elimination of floor clutter is important. Canes and other walking aids should

be recommended to patients with an unsteady gait. Physicians may need to overcome substantial patient resistance, but these aids can be lifesaving. Visual acuity should be maximized, and visual impairments corrected to the extent possible. Attention should be given to other comorbid conditions that may affect fracture risk, such as pain and depression, and the effects of medications that may cause diminished alertness and responsiveness by causing sedation or orthostatic hypotension.

C. Calcium   In the seventh decade and beyond, supplemental calcium and vitamin D therapy decrease bone turnover, increase bone mass, and have been shown in clinical trials to decrease fracture incidence. Studies confirming the clinical efficacy of various pharmacologic agents to increase BMD or decrease fracture have been performed in the setting of calcium and vitamin D sufficiency. Thus, adequate intake of calcium and vitamin D should be considered a basic approach for prevention and treatment of osteoporosis in all patients (Table 8–12).

The current recommended intake of calcium is 1300 mg/d for adolescents, 1000 mg/d for adult women up to age 50 and men up to age 70, and 1200 mg/d for women over age 50 and men over age 70. A dairy-free diet contains approximately 250 mg/d of calcium. Achieving the recommended calcium intake goals by food alone typically requires consumption of three to four servings per day of dairy foods or calcium-fortified foods. Patients who are unable to increase dietary calcium by diet alone may choose from many palatable, low-cost calcium preparations, the most frequently prescribed being the carbonate salt. Others include the lactate, gluconate, and citrate salts. Absorption of most commonly prescribed calcium products is similar. For many patients, cost and palatability outweigh modest differences in absorption. Calcium carbonate requires an acid environment for optimal absorption. For older individuals who may have hypo- or achlorhydria, taking calcium carbonate tablets with meals generally provides adequate acidity for this requirement. To maximize absorption, calcium should be taken in doses of 500 mg or less at a time and spread throughout the day. Calcium can interfere with the absorption of iron and L-thyroxine and should be ingested separately from these medications. There is no evidence that calcium intake beyond the current recommended levels results in additional benefits, and excessive supplemental intake modestly increases risk of nephrolithiasis. Concern has been raised about potential risk of cardiovascular events with calcium supplement use, although reports are inconsistent and this topic is controversial. A sensible approach is to encourage calcium from food sources and to use supplements only when necessary to attain the recommended total intake levels.

D. Vitamin D   In recent years, it has become necessary to reassess our concepts of vitamin D sufficiency (see also Vitamin D discussed earlier). Although circulating 25(OH)D concentrations above 10 ng/mL appear adequate for preventing histologic evidence of osteomalacia, a case has been made that values below 25 to 30 ng/mL may be associated with hypersecretion of PTH, proximal muscle weakness predisposing to falls, and increased bone turnover. In some regions of the United States, healthy adults show average 25(OH)D concentrations of 30 ng/mL or above, but in others, such as New England or in states farther north than Missouri, the ultraviolet component of sunlight fails to contain sufficient amounts, at the critical region of approximately 280 to 320 nm, to support cutaneous vitamin D synthesis. In those areas, vitamin D insufficiency is very common, particularly in frail, homebound, or hospitalized patients. Vitamin D supplementation in individuals with marginal or deficient vitamin D status improves intestinal calcium absorption, suppresses PTH and bone remodeling, and increases bone mass. In combination with calcium, it reduces fracture risk. Daily vitamin D supplementation may also reduce the risk of falls.

Pharmacologic Approaches to Osteoporosis Management

Drugs used for prevention and treatment of osteoporosis act either by decreasing the rate of bone resorption, thereby slowing the rate of bone loss, or by increasing bone formation (Table 8–13). Because of the coupling of bone resorption and formation, agents that decrease bone resorption ultimately decrease the rate of bone formation. Thus, increases in BMD, representing a reduction of

TABLE 8–12 Current recommendations for adequate daily intake of calcium and food sources of calcium.

Children/Adolescents	
Age 1-3	700 mg
Age 4-8	1000 mg
Ages 9-18	1300 mg

the remodeling space to a new steady-state level, are commonly observed during the first year or two of therapy, after which BMD increases slowly and may even reach a plateau. It is not uncommon for there to be minimal changes in BMD observed with treatment in clinical practice. Analysis of data from the Fracture Intervention Trial demonstrated that women treated with alendronate whose bone density did not increase during treatment still benefited, with rates of fracture reduction similar to the women whose BMD measurably increased. Thus, women on treatment with stable BMD should not be viewed as nonresponders or treatment failures.

Antiresorptive Agents

A. Estrogen   Conjugated equine estrogens (0.625 mg/d) increase BMD and reduce the risk of hip and vertebral fractures by about 35%. The Women's Health Initiative (WHI) demonstrated a lack of cardiovascular disease prevention in estrogen-treated postmenopausal woman and small but statistically significant increases in breast cancer and venous thromboembolic phenomena with estrogen and progesterone therapy (hormone therapy; HT) in postmenopausal women. These data led to a marked change in prescribing of HT for postmenopausal women such that only patients suffering from significant vasomotor effects of estrogen deficiency and early in menopause are now prescribed HT and for the shortest possible time. Reduced BMD is not considered an indication for HT, because effective alternative therapies for skeletal preservation exist. Low dose conjugated estrogens and estradiol increase BMD, but low dose therapy has not been tested for antifracture effects. Tibolone, which has estrogenic actions, is approved for osteoporosis treatment outside of the United States.

B. Selective estrogen response modulators   SERMs are molecules that act as estrogens on some tissues but antiestrogens on others. Raloxifene, the only SERM currently approved by the United States FDA for osteoporosis treatment, is an estrogen agonist at bone and liver, promoting conservation of BMD and lowering of LDL cholesterol concentrations. Raloxifene has been shown to decrease the vertebral fracture incidence in older osteoporotic women. It is inert at the endometrium and is a potent antiestrogen at the breast, decreasing breast cancer risk among high risk women. Side-effects include venous thromboembolism and hot flashes. Bazedoxifene, another SERM, is FDA-approved for the prevention (but not treatment) of osteoporosis in combination with estrogen.

C. Calcitonin   The role of endogenous calcitonin in calcium metabolism is unclear. However, given as a pharmacologic agent, calcitonin inhibits osteoclastic bone resorption. Intranasal and injectable formulations are approved for postmenopausal osteoporosis treatment. CT nasal spray (200 IU/d) increases BMD by 2% to 3% and reduces vertebral fractures by about 35%. CT has not been shown to reduce hip or nonspine fractures in randomized trials. CT may provide some analgesic benefit in patients with painful vertebral fractures, possibly through central nervous system effects. Side-effects of nasal spray CT appear mild and include rhinitis. Injectable CT may cause flushing, nausea, and local injection reactions, making the nasal option the preferred form of administration, but both formulations are used infrequently now that more potent agents are available.

D. Bisphosphonates   Bisphosphonates bind avidly to the hydroxyapatite crystals in bone, particularly at sites of active remodeling. The currently approved aminobisphosphonates interfere with protein prenylation in the osteoclast, impairing osteoclast-mediated bone resorption as well as enhancing osteoclast apoptosis. Four bisphosphonates, alendronate, risedronate, ibandronate, and zoledronic acid are FDA-approved for prevention and treatment of osteoporosis. Three of them (alendronate, risedronate, and zoledronic acid) are approved for treatment of glucocorticoid-induced osteoporosis in men and women and for the treatment of osteoporosis in men.

All the approved bisphosphonates have been shown to reduce vertebral fractures by approximately 50% to 60%. Alendronate, risedronate, and zoledronic acid have also been shown to reduce the risk of nonvertebral fractures. In clinical trials, hip fractures were reduced by 51% after treatment with alendronate, 30% after treatment with risedronate, and 41% after annual infusions of zoledronic acid for 3 years. Head-to-head comparisons, however, have not been performed. Treatment of individuals (men and women) who have had a hip fracture with zoledronic acid has also been shown to reduce subsequent fractures and decrease mortality in individuals. Ibandronate has not been shown to reduce the risk of nonvertebral fractures except in the post hoc analysis of women with T-scores less than −3. The fracture trials for all the bisphosphonates were conducted using daily dosing, except for zoledronic acid, which was given as a 5 mg annual intravenous dose. Based on equivalent effects on BMD to daily dosing, alendronate and risedronate are approved for weekly dosing, and risedronate and ibandronate are approved for monthly dosing. Ibandronate is also approved for quarterly intravenous dosing.

Oral bisphosphonate absorption is very low, less than 1% of the administered dose. Consequently, patients must take these medications on first arising in the morning, on an empty stomach with the exception of plain water, and ingest nothing else for 30 minutes for alendronate and risedronate, and 60 minutes for ibandronate. Side-effects from the oral bisphosphonates are primarily upper gastrointestinal, most notably esophageal irritation if the pill does not clear the esophagus. Hence, they must be taken with at least 8 oz of water, and a patient must remain upright to ensure passage of the pill into the stomach, and oral bisphosphonates are contraindicated in patients with clinically significant esophageal disease. Other bisphosphonate-related side-effects include bone pain and, for the intravenous agents, an acute phase reaction temporally related to dosing and typically limited to the patient's first dose. Bisphosphonate administration may precipitate hypocalcemia in patients with low levels of 25(OH)D. None of the bisphosphonates are recommended for use in patients with significant renal impairment (creatinine clearance <35 mL/min).

Two rare but serious side-effects have been reported with bisphosphonate therapy. Osteonecrosis of the jaw is an area of exposed bone in the maxillofacial region that did not heal within 8 weeks of identification by a health-care provider. The vast majority of cases have occurred after dental work in patients with malignancies on intravenous bisphosphonates at more frequent intervals and at much higher doses of drug than the annual infusions for patients with osteoporosis. Several cases, however, have been reported in patients with osteoporosis. Estimates of the incidence of this complication related to oral bisphosphonate treatment for osteoporosis appear to be between 1 in 10,000 and less than 1 in 100,000 patient-treatment years. Rates are significantly higher in malignant conditions such as multiple myeloma or breast cancer. Osteonecrosis of the jaw is a difficult disorder to treat, and suspected cases should be referred to an experienced dental professional. The other rare side-effect is the atypical femur fracture. This is defined as a fracture in the shaft or subtrochanteric region of the femur that originates at the lateral cortex and has a transverse orientation, is noncomminuted or minimally comminuted, shows lateral cortical thickening, and occurs with minimal or no trauma. Although the relative risk of patients with atypical femur fractures taking bisphosphonates is high, the absolute risk of these fractures with bisphosphonates is low. Long-term use of bisphosphonates may be associated with higher risk.

Duration of bisphosphonate therapy is a topic of great interest, but limited data exist about long-term use. One potential approach, based on limited evidence, is to reassess a patient's fracture risk after 5 years of oral or 3 years of intravenous bisphosphonate therapy. For those at high risk for fracture, continued therapy might be appropriate, while for those not at high risk, a drug holiday might be considered.

E. RANKL inhibition   Denosumab, a human monoclonal IgG2 antibody to RANKL, has been shown to reduce spine fractures by 68%, hip fractures by 40%, and nonvertebral fractures by 20% in postmenopausal women with low bone density (T-score <−2.5 and >−4.0). In the pivotal trial establishing this antifracture efficacy, 60 mg denosumab was administered subcutaneously every 6 months for 3 years. Denosumab has been approved by the FDA for the treatment of postmenopausal women and men with osteoporosis at high risk for fracture. Denosumab is also FDA-approved for the treatment of men at high risk for fracture receiving androgen deprivation therapy for nonmetastatic prostate cancer and of women at high risk for fracture receiving adjuvant aromatase inhibitor therapy for breast cancer. Adverse events include eczema and cellulitis. Rare cases of osteonecrosis of the jaw and atypical femur fractures have been reported with denosumab therapy.

Bone-Forming Agents

A. Parathyroid hormone   Fractures, skeletal deformity, and bone pain are well-described manifestations of bone disease associated with severe primary hyperparathyroidism. It may seem counterintuitive, therefore, that administration of PTH to individuals with low BMD not only improves BMD but also reduces the risk of fractures. Yet, this is the case. The decisive element that determines the effects of PTH to be destructive or therapeutic appears to be whether PTH concentrations in blood are elevated constantly or only intermittently. In severe hyperparathyroidism, PTH concentrations remain high, varying little throughout the day. Administration of PTH as daily pulse injections has been shown to increase BMD in both animals and humans, and abundant evidence now indicates that PTH is truly an osteotropic agent. In a large clinical trial conducted in postmenopausal women with osteoporosis, recombinant human PTH(1-34) (teriparatide), given in daily subcutaneous doses for approximately 21 months, reduced the incidence of vertebral fractures by more than 60% and that of nonvertebral fractures by 50%. During the course of this trial, a long-term carcinogenicity study showed that rats given very high daily injections of rhPTH(1-34) showed a dose-related incidence of osteosarcoma. Clinical studies with this agent were immediately suspended, until an independent group of cancer biologists concluded that the rat osteosarcoma finding was not likely to predict a relationship to osteosarcoma in humans, at which time human trials were resumed. Teriparatide is approved by the FDA for use in both men and postmenopausal women with osteoporosis who are at high risk for fractures as well as in glucocorticoid-induced osteoporosis. Therapeutic use is limited to 2 years and is recommended for individuals who have had a fracture related to osteoporosis, who have multiple risk factors for fracture, or who cannot use other osteoporosis treatments. Side-effects of PTH therapy include hypercalcemia, hypercalciuria, and bone pain, although they are infrequent. PTH therapy is contraindicated for patients with conditions placing them at increased risk for osteosarcoma such as Paget disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or patients who have received radiation therapy involving the skeleton. The very few reported cases of possible osteosarcoma approximate the background risk of osteosarcoma in the general population. After cessation of PTH therapy, bone loss resumes, and most if not all bone gained may be lost. It is strongly recommended that PTH therapy be followed with an antiresorptive agent, thus maintaining the gain in BMD achieved with PTH administration.

B. Other anabolic agents   PTH is the only anabolic agent approved by the FDA at this time, although other anabolic agents are under investigation. Outside the United States, strontium ranelate is used to treat osteoporosis.

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

In children, chronic exposure to glucocorticoids impairs skeletal growth. Glucocorticoid-induced deficits in childhood bone mass reflect failure of normal skeletal acquisition occasionally compounded by bone loss. In adults, initiation of glucocorticoid therapy leads to rapid bone loss, resulting in significant BMD

deficits within even a few months with a greater impact on trabecular than cortical bone. The magnitude of bone loss can be large, typically approaching 40% reduction of the initial BMD. Approximately half of long-term glucocorticoid-treated patients suffer a fracture. Skeletal fragility is not the only risk factor for fracture in steroid-treated patients, because glucocorticoids (and the illnesses for which they are prescribed) are also associated with muscle weakness, which itself creates instability and increases the risk of falling.

Glucocorticoid-induced bone loss generally follows sustained administration of systemic doses greater than 5 mg/d of prednisone or its equivalent. Short, infrequent courses of glucocorticoids, such as for poison oak dermatitis, do not appear to have long-term skeletal consequences. Used according to manufacturer recommendations, most steroid inhalers appear to be without skeletal consequence, because systemic absorption of glucocorticoids is minimal. However, excessive use of standard preparations may achieve systemic concentrations, adequate to suppress the hypothalamic-pituitary axis and predictably lead to loss of bone mass. Patients receiving maintenance hydrocortisone dosages (eg, 20 mg/d) for adrenocortical insufficiency do not generally have an increased skeletal risk. However, based on accurate measurements of steroid production rates in normal humans, maintenance doses of hydrocortisone are now estimated to be lower (ie, 15 mg/d) than have traditionally been recommended (about 30 mg/d). Patients who continue to be treated according to older recommendations may be at risk of excessive bone loss.

Pathophysiology

Glucocorticoids affect mineral balance through alterations in renal, intestinal, and skeletal function.

A. Renal calcium losses   Within a few days after initiating therapy, direct inhibition of renal tubular calcium reabsorption leads to hypercalciuria, which is magnified by excessive dietary sodium intake and attenuated by thiazide diuretics.

B. Intestinal calcium losses   Glucocorticoids, given in high doses for several weeks, inhibit intestinal calcium absorption, lowering plasma ionized $[Ca^{2+}]$. This is thought to stimulate compensatory hypersecretion of PTH, which restores serum ionized $[Ca^{2+}]$ by increasing the efficiency of renal calcium reabsorption and by activating bone turnover to increase delivery of calcium to the circulation from bone. However, it has never been shown consistently that plasma PTH concentrations are actually elevated in steroid-treated patients. Evidence suggests that PTH action in bone and kidney may be enhanced even if there are minimal or no increases in detectable PTH. PTH may contribute to the pathophysiology of bone loss in glucocorticoid-treated patients. Consistent effects of glucocorticoids on the production, clearance, and circulating concentrations of vitamin D metabolites have not been demonstrable, so it appears that the intestinal actions of glucocorticoids are independent of the vitamin D system.

C. Skeletal losses   Glucocorticoids affect the skeleton by multiple mechanisms. There is evidence for direct stimulation of bone resorption via increased RANKL expression and decreased OPG production. Glucocorticoids also inhibit osteoblastic maturation and activity. Recent information indicates that glucocorticoids shift multipotent stem cell maturation away from osteoblastic lineage toward other cell lines, particularly adipocytes. Glucocorticoids also promote apoptosis in osteoblasts and osteocytes. In patients chronically treated with glucocorticoids, bone formation is suppressed. High-dose glucocorticoid administration also suppresses gonadotropin secretion and creates a hypogonadal state in both men and women. Thus, a component of the bone loss in some steroid-treated patients is likely to be related to loss of gonadal function.

Prevention and Treatment of Glucocorticoid-Related Osteoporosis

A. Reduction of steroid dose   Prevention of bone loss remains the approach most likely to give a favorable outcome. The most important aspect of a preventive strategy is to limit exposure to glucocorticoids and to find alternative treatments if possible. Opportunities should be sought for initiating dose reduction or switching to nonsystemic forms of steroid administration. Unfortunately, the use of alternate-day steroids, which is known to protect growth in steroid-treated children, appears not to offer skeletal protection to adults. The possibility that a bone-sparing glucocorticoid might be developed has been under consideration for many years, but no such agent is currently available. In patients who require immunosuppression following organ transplantation, the use of cyclosporine and tacrolimus has permitted reductions in glucocorticoid use. However, these other drugs also have been associated with lower BMD; whether long-term therapy will have less negative skeletal effects than glucocorticoids is not established.

B. Calcium and vitamin D   Providing supplemental calcium and vitamin D to glucocorticoid-treated patients normalizes serum ionized $[Ca^{2+}]$, suppresses PTH secretion, and reduces bone remodeling, thereby reducing the number of active remodeling units at a given time. So long as the patient continues to take glucocorticoids, however, suppression of osteoblast function does not reverse. Patients should receive 1200 mg/d of supplemental calcium on the condition that such supplementation does not result in hypercalciuria. Vitamin D dosing should be targeted to maintain "therapeutic" 25(OH)D levels. However, periodic surveillance of glucocorticoid-treated patients for urinary calcium excretion is warranted, because they are at higher risk of developing kidney stones as a consequence of hypercalciuria.

C. Physical activity   Skeletal immobilization precipitates bone loss, so inactivity must be avoided in steroid-treated patients. Some conditions such as polymyalgia rheumatica respond exuberantly to steroid therapy, giving patients a rapid

and complete recovery of function. These patients may have little difficulty maintaining a vigorous schedule of weight-bearing activities during treatment. Patients with other conditions may not regain full mobility and may have residual functional disabilities. It is particularly important that such patients receive physical therapy or other appropriate support for maintaining and restoring functional capacity.

D. Hormone therapy   Glucocorticoids decrease sex steroid production, so evaluation of gonadal hormone status should be considered in all glucocorticoid-treated patients. In some rheumatologic conditions (eg, systemic lupus erythematosus), estrogens have traditionally been avoided. If there are no contraindications, then estrogen/progestin replacement may be considered in premenopausal women with amenorrhea and hypoestrogenism, and testosterone should be considered for men with hypogonadism.

Pharmacologic Therapy of Glucocorticoid-Related Osteoporosis

Alendronate, risedronate, zoledronic acid, and teriparatide have been shown to increase BMD and decrease the risk of new vertebral fractures by up to 70% in patients on glucocorticoid therapy.

Because the bone loss associated with glucocorticoid therapy has a very rapid onset and occurs in approximately 50% of treated patients, starting a bisphosphonate or teriparatide along with the glucocorticoid therapy may be appropriate. It is prudent to assess BMD and to estimate fracture risk in patients beginning glucocorticoid therapy. Whether to initiate an antiosteoporosis medication and which agent to begin may then be decided based on baseline fracture risk, glucocorticoid dose, and anticipated duration of glucocorticoid therapy. Serial BMD assessment is warranted, with the frequency of testing influenced by whether or not osteoporosis therapy has already been initiated, the results of previous BMD testing, and glucocorticoid dose.

OSTEOMALACIA AND RICKETS

Osteomalacia and rickets are caused by the abnormal mineralization of bone and cartilage. Osteomalacia is a bone defect occurring after the epiphyseal plates have closed (ie, in adults). Rickets occurs in growing bone (ie, in children). Abnormal mineralization in growing bone affects the transformation of cartilage into bone at the zone of provisional calcification. As a result, an enormous profusion of disorganized, nonmineralized, degenerating cartilage appears in this region, leading to widening of the epiphyseal plate (observed radiologically as a widened radiolucent zone) with flaring or cupping and irregularity of the epiphyseal-metaphyseal junctions. This latter problem gives rise to the clinically obvious beaded swellings along the costochondral junctions known as the **rachitic rosary** and the swelling at the ends of the long bones. Growth is retarded by the failure to make new bone. Once bone growth has ceased (ie, after closure of the epiphyseal plates), the clinical evidence for defective mineralization becomes more subtle, and special diagnostic procedures may be required for its detection.

Pathogenesis

The best-known cause of abnormal bone mineralization is vitamin D deficiency (discussed earlier). Vitamin D, through its biologically active metabolites, ensures that the calcium and phosphate concentrations in the extracellular milieu are adequate for mineralization. Vitamin D may also permit osteoblasts to produce a bone matrix that can be mineralized and then allows them to mineralize that matrix normally. Phosphate deficiency can also cause defective mineralization, as in diseases in which phosphate is lost in the urine or poorly absorbed in the intestine. A number of hypophosphatemic conditions result from excess circulating FGF23 that can both decrease 1-hydroxylase activity and renal phosphate reabsorption. Phosphate deficiency may act independently or in conjunction with other predisposing abnormalities, because most hypophosphatemic disorders associated with osteomalacia or rickets also affect the vitamin D endocrine system. Dietary calcium deficiency has been shown to lead to rickets in children in the absence of vitamin D deficiency and may contribute to the osteomalacia of elderly adults who are also susceptible to vitamin D deficiency.

Osteomalacia or rickets may develop despite adequate levels of calcium, phosphate, and vitamin D if the bone matrix cannot undergo normal mineralization as a result of enzyme deficiencies, such as decreased alkaline phosphatase in patients with hypophosphatasia, or in the presence of inhibitors of mineralization, such as aluminum, fluoride, or etidronate. Table 8–14 lists diseases associated with osteomalacia or rickets according to their presumed mechanism. Several diseases appear under several headings, indicating that they contribute to bone disease by several mechanisms.

Diagnosis

The following discussion refers primarily to vitamin D deficiency. In children, the presentation of rickets is generally obvious from a combination of clinical and radiologic evidence. The diagnostic challenge is to determine the cause. In adults, the clinical, radiologic, and biochemical evidence of osteomalacia is often subtle. In situations in which osteomalacia should be suspected such as malnutrition or malabsorption, BMD is strikingly low, and the clinician must decide whether to obtain a bone biopsy for histomorphometric examination. This decision rests on the availability of resources to obtain and examine the biopsy specimen, the index of suspicion coupled with the lack of certainty from other diagnostic procedures, and the degree to which the therapeutic approach will be altered by the additional information. In many cases, a therapeutic trial of vitamin D supplements suffices to establish the diagnosis without the need for bone biopsy.

Clinical Features

A. Symptoms and signs   The clinical presentation of rickets depends on the age of the patient and, to some extent, the

TABLE 8–14 Causes of osteomalacia.

Disorders of the Vitamin D Endocrine System
Decreased bioavailability
Insufficient sunlight exposure
Nutritional vitamin D deficiency
Nephrotic syndrome (urinary loss)
Malabsorption (fecal loss)
Billroth type II gastrectomy
Sprue
Regional enteritis
Bariatric surgery
Pancreatic insufficiency
Cholestatic disorders
Cholestyramine
Abnormal metabolism
Liver disease
Chronic renal failure
Pseudovitamin D deficiency rickets
Tumor-induced osteomalacia
X-linked hypophosphatemia
Autosomal dominant hypophosphatemic rickets
Chronic acidosis
Anticonvulsants
Abnormal target tissue response
Hereditary vitamin D deficient rickets
Gastrointestinal disorders
Disorders of Phosphate Homeostasis
Decreased intestinal absorption
Malnutrition
Malabsorption
Antacids containing aluminum hydroxide
Diarrhea
Increased renal loss
X-linked hypophosphatemic rickets
Autosomal dominant hypophosphatemic rickets
Autosomal recessive hypophosphatemic rickets
Mutations in renal phosphate transporters (SLC34A1, SLC34A3, SLC20A2)
Tumor-induced osteomalacia
De Toni-Debré-Fanconi syndrome
Calcium Deficiency
Primary Disorders of Bone Matrix
Hypophosphatasia
Fibrogenesis imperfecta ossium
Axial osteomalacia
Inhibitors of Mineralization
Aluminum
Chronic renal failure
Total parenteral nutrition
Etidronate
Fluoride

FIGURE 8–28 The clinical appearance of a young child with rickets. The most striking abnormalities are the bowing of the legs and protuberant abdomen. Flaring of the ends of the long bones can also be appreciated. (Used with permission from Dr. Sara Arnaud.)

cause of the syndrome. The affected infant or young child may be apathetic, listless, weak, hypotonic, and growing poorly. A soft, somewhat misshapen head, with widened sutures and frontal bossing, may be observed. Eruption of teeth may be delayed, and teeth that do appear may be pitted and poorly mineralized. The enlargement and cupping of the costochondral junctions produce the rachitic rosary on the thorax. The tug of the diaphragm against the softened lower ribs may produce an indentation at the point of insertion of the diaphragm (Harrison groove).

Muscle hypotonia can result in a pronounced potbelly and a waddling gait. The limbs may become bowed, and joints may swell because of flaring at the ends of the long bones (including phalanges and metacarpals) (Figure 8–28). Pathologic fractures may occur in patients with florid rickets. After the epiphyses have closed, the clinical signs of rickets or osteomalacia are subtle and cannot be relied on to make the diagnosis. Patients with severe osteomalacia complain of bone pain and proximal muscle weakness. Difficulty climbing stairs or rising from chairs may be reported and should be looked for. Such individuals may have a history of fractures and be diagnosed as having osteoporosis.

B. Laboratory findings

1. **Biochemistry**—Vitamin D deficiency results in decreased intestinal absorption of calcium and phosphate. In conjunction with the resulting secondary hyperparathyroidism, vitamin D deficiency leads to an increase in bone resorption, increased excretion of urinary phosphate, and increased renal tubular reabsorption of calcium. The net result tends to be low-normal serum calcium, low serum phosphate, elevated serum alkaline phosphatase, increased plasma PTH, decreased urinary calcium, and increased urinary phosphate levels. Finding a low serum 25(OH)D level, in combination with these other biochemical alterations, strengthens the diagnosis of vitamin D deficiency. The serum 1,25(OH)$_2$D level may be normal, making this determination less useful for the diagnosis of osteomalacia. Both 25(OH)D and 1,25(OH)$_2$D levels may be reduced in patients with liver disease or nephrotic syndrome because the binding proteins for the vitamin D metabolites are low

secondary to decreased production (liver disease) or increased renal losses (nephrotic syndrome; discussed later). Such individuals may have normal free concentrations of these metabolites and so are not vitamin D-deficient. Other factors, such as age and diet, must be considered. For example, serum phosphate values are normally lower in adults than in children. Dietary history is important, because urinary phosphate excretion and, to a lesser extent, urinary calcium excretion reflect dietary phosphate and calcium content. Because phosphate excretion depends on the filtered load (the product of the glomerular filtration rate and plasma phosphate concentration), urinary phosphate levels may be reduced despite the presence of hyperparathyroidism, when serum phosphate levels are particularly low. Expressions of renal phosphate clearance that account for these variables (eg, renal threshold for phosphate, or TmP/GFR) are a better indicator of renal phosphate handling than is total phosphate excretion. The TmP/GFR can be calculated from a nomogram using measurements of a fasting serum and urine phosphate concentration.

2. **Histologic examination**—Transcortical bone biopsy is the definitive means of making the diagnosis of osteomalacia. A rib or the iliac crest is the site at which biopsy is usually performed. To assess osteoid content and mineral appositional and bone formation rates, the bone biopsy specimen is processed without decalcification. This requires special equipment. In osteomalacia, bone is mineralized poorly and slowly, resulting in wide osteoid seams (>12 μm) and a large fraction of bone covered by unmineralized osteoid. States of high bone turnover (increased bone formation and resorption), such as hyperparathyroidism, can also cause wide osteoid seams and an increased osteoid surface, producing a superficial resemblance to osteomalacia. Therefore, the rate of bone turnover should be determined by labeling bone with tetracycline, which provides a fluorescent marker of the calcification front. When two doses of tetracycline are given at different times, the distance between the two labels divided by the time interval between the two doses equals the mineral appositional rate. The normal appositional rate is approximately 0.74 μm/d. Mineralization lag time—the time required for newly formed osteoid to be mineralized—can be calculated by dividing osteoid seam width by the appositional rate corrected by the linear extent of mineralization of the calcification front (a measure of the bone surface that is undergoing active mineralization as measured by tetracycline incorporation). Mineralization lag time is normally about 20 to 25 days. Bone formation rate is calculated as the product of the appositional rate times the linear extent of mineralization of the calcification front. Depressed appositional rate, increased mineralization lag time, and reduced bone formation rate clearly distinguish osteomalacia from high-turnover states such as hyperparathyroidism. Low-turnover states, as can be seen in various forms of osteoporosis, also have low appositional and bone formation rates, but these conditions are distinguished from osteomalacia by normal or reduced osteoid surface and volume.

C. Imaging studies   The radiologic features of rickets can be quite striking, especially in the young child. In growing bone, the radiolucent epiphyses are wide and flared, with irregular epiphyseal-metaphyseal junctions. Long bones may be bowed. The cortices of the long bones are often indistinct. Occasionally, evidence of secondary hyperparathyroidism—subperiosteal resorption in the phalanges and metacarpals and erosion of the
FIGURE 8–29   X-ray of the pelvis of an elderly woman with osteomalacia. Note marked bowing of both femoral necks, with pseudofractures of the medial aspect of the femoral necks and the superior aspect of the left pubic ramus (arrows). (Used with permission from Dr. Harry Genant.)

distal ends of the clavicles—is observed. Pseudofractures (also known as Looser zones or Milkman fractures) are an uncommon but nearly pathognomonic feature of rickets and osteomalacia (Figure 8–29). These radiolucent lines are most often found along the concave side of the femoral neck, pubic rami, ribs, clavicles, and lateral aspects of the scapulae. Pseudofractures may result from unhealed microfractures at points of stress or at the entry point of blood vessels into bone. They may progress to complete fractures that go unrecognized and thus lead to substantial deformity and disability. BMD is not a reliable indicator of osteomalacia, because BMD can be decreased in patients with vitamin D deficiency or increased in patients with chronic renal failure. In adults with normal renal function, radiologic evidence of a mineralization defect is often subtle and not readily distinguished from osteoporosis, with which it often coexists.

Treatment

The treatment of vitamin D deficiency is covered under that heading. The treatment of other diseases causing rickets or osteomalacia is found below under the specific disease headings.

NEPHROTIC SYNDROME

Nephrotic syndrome may lead to osteomalacia because of losses of vitamin D metabolites in the urine. Vitamin D metabolites are tightly bound to DBP, an α-globulin, and less tightly bound to albumin as described earlier. Patients with the nephrotic syndrome may lose large amounts of DBP and albumin in their urine and so deplete their vitamin D stores. Such patients can have very low levels of vitamin D metabolites in their serum, although the free concentrations are less affected. Thus, the measurement of total 25(OH)D or 1,25(OH)$_2$D may be misleading with respect to the severity of the vitamin D deficiency. Although bone disease has been recognized as a complication of the nephrotic syndrome, the prevalence of osteomalacia in this population is unknown. If vitamin D deficiency is suspected, treatment with vitamin D is

indicated with the proviso that normal total levels of 25(OH)D and $1,25(OH)_2D$ are not the goal. Serum and urine levels of calcium and phosphate, and plasma PTH levels are a more reliable guide to treatment.

HEPATIC OSTEODYSTROPHY

Hepatic osteodystrophy is the bone disease associated with liver disease. In the United States, patients with severe liver disease generally have osteoporosis, not osteomalacia. Both osteomalacia and osteoporosis are found in patients with liver disease in Great Britain, where vitamin D deficiency is more common. Although the liver is the site of the first step in the bioactivation of vitamin D—the conversion of vitamin D to 25(OH)D—this process is not tightly controlled, and until the liver disease is severe it is not rate limiting. Neither cholestatic nor parenchymal liver disease has much effect on 25(OH)D production until the late stages of liver failure. The low levels of 25(OH)D and $1,25(OH)_2D$ associated with liver disease can usually be attributed to the reduced production of DBP and albumin, poor nutrition, or malabsorption rather than a deficiency in the vitamin D 25-hydroxylase. As in patients with the nephrotic syndrome, the low total levels of the vitamin D metabolites may be misleading, as they reflect a reduction in DBP and albumin rather than a reduction in the free concentrations of these metabolites, which in several studies have been shown to be normal.

DRUG-INDUCED OSTEOMALACIA

Phenytoin and phenobarbital are anticonvulsants that induce drug-metabolizing enzymes in the liver that alter the hepatic metabolism of vitamin D and its metabolites. This action is not limited to anticonvulsants; the antituberculosis drug rifampin has been reported to do likewise. This effect may account for the lower circulating levels of 25(OH)D found in patients treated with such drugs. Levels of $1,25(OH)_2D$ are less affected. These therapies do not appear to lead to clinically significant bone disease except in subjects with other predisposing factors such as inadequate sunlight exposure (institutionalized patients) and poor nutrition. Children may be more vulnerable than adults. In animal studies, phenytoin has been noted to exert a direct inhibitory effect on bone mineralization, but the relevance of this observation to the human use of this drug is uncertain. The decrease in 25(OH)D levels in patients taking these drugs can be readily reversed with supplemental vitamin D administration.

HYPOPHOSPHATEMIC DISORDERS

Chronic hypophosphatemia may lead to rickets or osteomalacia independently of other predisposing abnormalities. The principal diseases in which hypophosphatemia is associated with osteomalacia or rickets, however, also include other abnormalities that can interfere with bone mineralization. Chronic phosphate depletion is caused by dietary deficiency (as in strict vegetarians), decreased intestinal absorption, or increased renal clearance (renal wasting). Acute hypophosphatemia can result from movement of phosphate into cells (eg, after infusion of insulin and glucose), but this condition is transient and does not result in bone disease.

Seventy to ninety percent of dietary phosphate is absorbed under normal conditions in the jejunum. This process is not tightly regulated, although $1,25(OH)_2D$ stimulates phosphate absorption, a factor that needs to be considered when calcitriol is being used to treat other conditions. Meat and dairy products are the principal dietary sources of phosphate. The incidence of osteomalacia in vegetarians who avoid all meat and dairy products is unknown, but when combined with low vitamin D production (decreased sunlight exposure) or intake as in East Asian immigrants in temperate countries such as England, osteomalacia is common. Intrinsic small bowel disease and small bowel surgery interfere with phosphate absorption and, if coupled with diarrhea or steatorrhea, can result in phosphate depletion. Antacids that contain aluminum hydroxide can bind phosphate and prevent its absorption. Patients who ingest large amounts of these antacids may become phosphate depleted. When this occurs in the setting of renal failure, reductions in serum phosphate plus aluminum intoxication in these individuals, who also have reduced $1,25(OH)_2D$ production, can produce profound osteomalacia. Fortunately this complication of these drugs is now well recognized, and use of such antacids as phosphate binders has declined. Eighty-five to ninety percent of the phosphate filtered by the glomerulus is reabsorbed, primarily in the proximal tubule. This process is regulated by PTH which reduces renal tubular phosphate reabsorption. It is also probably regulated by various vitamin D metabolites that appear to increase renal tubular phosphate reabsorption, and importantly by FGF23, which blocks the insertion of sodium phosphate cotransporters into the luminal membrane of renal proximal tubular cells, thus limiting renal phosphate reabsorption. Many diseases that affect renal handling of phosphate are associated with osteomalacia—especially those also associated with abnormalities in vitamin D metabolism and in FGF23 production and/or clearance, as discussed later (see also Chapter 21).

Treatment of phosphate deficiency is generally geared to correction of the primary problem. Oral preparations of phosphate (and the amounts required to provide 1 g of elemental phosphorus) include Fleet Phospho-soda (6.12 mL) and Neutra-Phos (300 mL). These preparations are usually given in amounts that provide 1 to 3 g of phosphorus daily in divided doses, although diarrhea may limit the dose. Careful attention to both serum calcium and serum phosphate concentrations is required to avoid hypocalcemia, ectopic calcification, or secondary hyperparathyroidism.

X-Linked and Autosomal Dominant Hypophosphatemia

X-linked hypophosphatemia (XLH), formerly called vitamin D-resistant rickets, is characterized by renal phosphate wasting, hypophosphatemia, and decreased $1,25(OH)_2D$ production relative to the degree of hypophosphatemia. Clinical presentation is variable, but children often present with florid rickets. This X-linked

dominant disorder generally affects males more severely than females. A similar but genetically distinct syndrome, autosomal dominant hypophosphatemic rickets (ADHR), is less common, affects females to the same extent as males, and may present later in life (second to fourth decades). The primary cause of hypophosphatemia in both conditions is excess FGF23. Circulating FGF23 is responsible for both the reduction in phosphate reabsorption in the renal proximal tubule and the blunted response of the proximal tubule to the ensuing hypophosphatemia with respect to $1,25(OH)_2D$ production. The gene responsible for XLH is *PHEX*. It shares structural homology with a number of endopeptidase genes and is located on the X chromosome. As is implicit in this ambiguous name, the role of PHEX in renal phosphate transport is not clear. The prevailing hypothesis is that PHEX indirectly leads to the cleavage and subsequent inactivation of FGF23, thus relieving the inhibition of phosphate reabsorption and $1,25(OH)_2D$ production.

ADHR is due to a mutation in FGF23 that renders it resistant to cleavage. Recent evidence suggests that the defects in XLH and ADHR may not be restricted to the proximal renal tubule but may affect osteoblast function as well, a cell in which *PHEX* is expressed.

Treatment of XLH and ADHR generally requires a combination of phosphate (1-4 g/d in divided doses) combined with calcitriol (1-3 μg/d) as tolerated. Vitamin D is less effective than calcitriol and should not be used for this condition. Recent studies with a neutralizing antibody to FGF23 in patients with XLH show promise and may help reduce the doses of calcitriol and phosphate required to treat this condition and ultimately achieve better control of the biochemical parameters. Appropriate therapy heals the rachitic lesions and increases growth velocity. A frequent complication of these diseases, however, is the development of hyperparathyroidism, which may become autonomous and require parathyroidectomy. It is unclear whether the hyperparathyroidism is a complication of therapy or intrinsic to the disease process itself. Treatment with phosphate and calcitriol may also lead to ectopic calcification, including nephrocalcinosis. Thus, these patients need to be followed closely.

Tumor-Induced Osteomalacia

The association of osteomalacia and hypophosphatemia with tumors, primarily of mesenchymal origin, has been recognized for half a century (see Chapter 21). The cause of this syndrome has until recently remained obscure. Removal of the tumors, which are often small and difficult to find, cures the disease. Although most implicated tumors are mesenchymal, including fibromas and osteoblastomas, other tumors, including breast, prostate, and lung carcinomas; multiple myeloma; and chronic lymphocytic leukemia have been associated with this syndrome. The patient generally presents with bone pain, muscle weakness, and osteomalacia. Symptoms may occur for years before the diagnosis is made. Renal phosphate wasting, hypophosphatemia, and normal serum calcium and 25(OH)D levels but inappropriately low $1,25(OH)_2D$ levels characterize the disease. Thus, it resembles XLH and ADHR. Tumor extracts contain molecules that inhibit renal phosphate transport and $1,25(OH)_2D$ production, suggesting that a phosphate-regulating substance or **phosphatonin** is involved. Thus, it was of great interest to observe that many of these tumors overproduce FGF23 and that production by the tumor of FGF23 can explain the metabolic abnormalities associated with the hypophosphatemic syndrome (see Figure 8–10). Other tumor products such as MEPE (matrix extracellular phosphoglycoprotein) and sFRP4 (secreted frizzled related protein 4) have also been implicated. The best treatment is removal of the tumor, but this is not always possible. Phosphate and calcitriol have been the mainstays of treatment but with limited success. Patients should be dosed to tolerance as in XLH and ADHR.

Fibrous Dysplasia

Fibrous dysplasia results from activating mutations in the *GNAS* gene, which encodes Gs alpha. Fibrous dysplasia of bone is a component of the McCune-Albright syndrome. The bony lesions in this disorder overproduce FGF23 which like tumor-induced osteomalacia, described earlier, leads to hypophosphatemia, osteomalacia, and inappropriately normal $1,25(OH)_2D$. These lesions can be mono-ostotic or polyostotic, with the extent of bone involved correlating with the degree of FGF23 hypersecretion, and hence the hypophosphatemia observed.

De Toni-Debré-Fanconi Syndrome and Hereditary Hypophosphatemic Rickets with Hypercalciuria

The De Toni-Debré-Fanconi syndrome includes a heterogeneous group of disorders affecting the proximal tubule and leading to phosphaturia and hypophosphatemia, aminoaciduria, glycosuria, bicarbonaturia, and proximal renal tubular acidosis. Not all features must be present to make the diagnosis. Damage to the renal proximal tubule secondary to genetic or environmental causes is the underlying cause. Drugs that cause the renal Fanconi syndrome include antiretrovirals such as tenofovir and adefovir (see Chapter 25), the alkylating agent ifosfamide, cisplatin, valproic acid, and the antibiotics gentamicin and tetracycline. Genetic causes of an autosomal recessive Fanconi syndrome include a duplication of *SLA34A1,* which encodes NaPiIIa, but how this leads to a generalized proximal tubular dysfunction is not clear. This syndrome may be divided into two types depending on whether vitamin D metabolism is also abnormal. In the more common type I, $1,25(OH)_2D$ production is reduced relative to the degree of hypophosphatemia, similar to that seen in XLH. In type II, $1,25(OH)_2D$ production is appropriately elevated in response to the hypophosphatemia, and this leads to hypercalciuria, similar to that seen in hereditary hypophosphatemic rickets with hypercalciuria (HHRH). The reason that $1,25(OH)_2D$ production is reduced in type I, despite the hypophosphatemia, is unclear but may suggest damage to the mitochondria where the 1-hydroxylase is located.

As noted earlier, the type II Fanconi syndrome shares the principal features of HHRH. This latter rare disorder results from mutations in *SLC34A3,* the gene that encodes the type IIc sodium

phosphate cotransporter (NaPiIIc), leading to loss of function of this transporter. Mutations in NaPiIIa, the other major renal sodium phosphate cotransporter, produces a similar picture. The key difference between HHRH and ADHR or XLH is that FGF23 is not elevated—so 1-hydroxylase activity is not suppressed. Thus, the hypophosphatemia leads to increased $1,25(OH)_2D$ production, increased intestinal calcium absorption, and hypercalciuria. HHRH is heterogeneous in clinical presentation, but in severely affected individuals, it begins in childhood with bone pain and skeletal deformities. The syndrome is characterized by renal phosphate wasting and hypophosphatemia, hypercalciuria and normal serum calcium, and elevated $1,25(OH)_2D$ levels.

The osteomalacia associated with these renal phosphate-wasting syndromes is probably the result of the hypophosphatemia, with contributions from the acidosis and decreased $1,25(OH)_2D$ levels in the type I syndrome.

The ideal treatment is correction of the underlying defect, which may or may not be identified and/or reversible. Otherwise, treatment includes phosphate supplementation in all cases, correction of the acidosis, and $1,25(OH)_2D$ replacement in the type I syndrome, but not in HHRH as this will aggravate the hypercalciuria.

CALCIUM DEFICIENCY

Calcium deficiency may contribute to the mineralization defect that complicates gastrointestinal disease and proximal tubular disorders, but it is less well established as a cause of osteomalacia than is vitamin D or phosphate deficiency. In carefully performed studies of children who ingested a very low-calcium diet in Africa, there was clinical, biochemical, and histologic evidence of osteomalacia. The serum phosphate, 25(OH)D and $1,25(OH)_2D$ levels were normal; serum alkaline phosphatase levels were elevated; and serum and urine calcium levels were low. Because the efficiency of intestinal absorption of calcium decreases with age, the daily requirement for calcium increases from approximately 1000 mg in young adults to 1200 mg in the elderly. Calcium deficiency can result not only from inadequate dietary intake but also from excessive fecal and urinary losses. Except in cases in which a renal leak of calcium plays an important role in the etiology of calcium deficiency (certain forms of idiopathic hypercalciuria or following glucocorticoid therapy for inflammatory diseases), urinary calcium excretion provides a useful means to determine the appropriate level of oral calcium replacement. Because of its low cost and high percentage of elemental calcium, calcium carbonate is the treatment of choice, although calcium citrate may be better absorbed on an empty stomach and is less constipating.

PRIMARY DISORDERS OF THE BONE MATRIX

Several diseases lead to abnormalities in bone mineralization because of intrinsic defects in the matrix or in the osteoblast producing that matrix. With the exception of osteogenesis imperfecta, these tend to be rare. Examples are listed later.

OSTEOGENESIS IMPERFECTA

The classic forms of osteogenesis imperfecta (OI) are heritable disorders of connective tissue due to qualitative or quantitative abnormalities in type I collagen, the most abundant collagen in bone. The disease is typically transmitted in an autosomal dominant mode, although autosomal recessive inheritance has also been described in the forms of OI due to mutations in genes encoding noncollagenous proteins. The clinical phenotype of OI is highly variable, depending on the location and type of mutation observed. Although skeletal deformity and fracture are the hallmarks of this disease, other tissues are often affected, including the teeth, skin, ligaments, and scleras. Routine biochemical studies of bone and mineral metabolism are generally normal; however, elevated serum alkaline phosphatase and increased excretion of biochemical markers of bone turnover and calcium are often found. Bone histology shows abundant disorganized, poorly mineralized matrix but sometimes with a high rate of bone turnover as reflected by increased tetracycline labeling.

Treatment is supportive and includes orthopedic, rehabilitative, and dental intervention as appropriate. Bisphosphonates have recently been shown to be of value in children to prevent fractures and reduce bone pain and skeletal morbidity. Bisphosphonates have also been tested used in adults, often in the setting of fragility fractures, as well as teriparatide as a therapy to rebuild bone microarchitecture and mass.

Hypophosphatasia

Hypophosphatasia, transmitted in an autosomal recessive or dominant pattern, has considerable variability in clinical expression ranging from a severe form of rickets in children to a predisposition to fractures in adults. The biochemical hallmarks are low serum and tissue levels of alkaline phosphatase (liver-bone-kidney but not intestine-placenta) and increased urinary levels of phosphoethanolamine. Serum calcium and phosphate levels may be high, and many patients have hypercalciuria. Levels of vitamin D metabolites and PTH are generally normal. In some families, a mutation in the *tissue nonspecific alkaline phosphatase* gene has been identified. Radiologic examination shows osteopenia, with the frequent occurrence of stress fractures and chondrocalcinosis. Bone biopsy specimens show osteomalacia. Skeletal alkaline phosphatase cleaves pyrophosphate, an inhibitor of bone mineralization. Thus, patients deficient in alkaline phosphatase may be unable to hydrolyze this inhibitor and so develop a mineralization defect. Current therapy in severe cases involves the administration of asfotase alfa, a recombinant form of alkaline phosphatase.

Fibrogenesis Imperfecta Ossium

Fibrogenesis imperfecta ossium is a rare, painful disorder that affects middle-aged subjects in what appears to be a sporadic fashion. Serum alkaline phosphatase activity is increased. The bones have a dense, amorphous mottled appearance radiologically and a disorganized arrangement of collagen with decreased birefringence

histologically when viewed with polarized light microscopy. Presumably, the disorganized collagen matrix retards normal bone mineralization. There is no specific therapy.

INHIBITORS OF MINERALIZATION

Several drugs are known to cause osteomalacia or rickets by inhibiting mineralization. However, the mechanisms by which this occurs are not fully understood.

Aluminum

Aluminum-induced bone disease is found primarily in patients with renal failure on chronic hemodialysis or in patients being treated with total parenteral nutrition (TPN). With the recognition of this complication and the switch to deionized water for dialysis, elimination of aluminum-containing antacids, and the use of purified amino acids rather than casein hydrolysates (which contained large amounts of aluminum) for TPN, the incidence and prevalence of this complication have been markedly reduced. The problem, however, still exists. As described under renal osteodystrophy, the bone disease is osteomalacia and can be severe and painful. Aluminum deposits in the mineralization front and appears to inhibit the mineralization process. Removal of the aluminum with deferoxamine chelation therapy is the treatment of choice.

Fluoride

Fluoride is a potent stimulator of bone formation. If administered at high doses with inadequate calcium supplementation, the bone formed as a result is poorly mineralized. The mechanisms underlying the effects of fluoride on osteoblast function and bone mineralization remain unclear.

PAGET DISEASE OF BONE (OSTEITIS DEFORMANS)

Paget disease is a focal disorder of bone remodeling that leads to greatly accelerated rates of bone turnover, disruption of the normal architecture of bone, and sometimes to gross deformities of bone. As a focal disorder it is not, strictly speaking, a metabolic bone disease. Paget disease is prevalent in northern Europe, particularly in England and Germany. It is also common in the United States but is unusual in Africa and Asia.

Etiology

It has long been thought that Paget disease, with its late onset and spotty involvement of the skeleton, might be due to a chronic slow virus infection of bone. Inclusion bodies that resemble paramyxovirus inclusions have been identified in pagetic osteoclasts, and the presence of measles virus transcripts has been detected by molecular techniques. However, considerably more work would be required to prove the infectious etiology of Paget disease. There are also familial clusters of the disease, with up to 20% of patients in some studies having afflicted first-degree relatives so several pathogenetic mechanisms are likely (discussed later).

Pathology

At the microscopic level, the disorder is characterized by highly vascular and cellular bone, consistent with its high metabolic activity. The osteoclasts are sometimes huge and bizarre, with up to 100 nuclei per cell. Because pagetic osteoclasts initiate the bone remodeling cycle in a chaotic fashion, the end result of remodeling is a mosaic pattern of lamellar bone. Paget disease (and other high turnover states) can also produce woven bone—bone that is laid down rapidly and in a disorganized fashion, without the normal lamellar architecture.

Pathogenesis

Abnormal osteoclastic bone resorption is the probable initiating event in Paget disease. Not only are the osteoclasts abnormal histologically and prone to unruly behavior, but some forms of the disease are marked by an early resorptive phase in which pure osteolysis occurs without an osteoblastic response. Additionally, Paget disease responds dramatically to inhibitors of osteoclastic bone resorption.

The rate of bone resorption is often increased by as much as 10- to 20-fold, and this is reflected in biochemical indices of bone resorption. Over the skeleton as a whole, osteoblastic new bone formation responds appropriately to this challenge. Even though local disparities in remodeling may result in areas with the radiographic appearance of osteolysis or dense new bone, there is a close relationship between biochemical markers of bone resorption (eg, N-telopeptide, C-telopeptide, deoxypyridinoline) and formation (eg, alkaline phosphatase, osteocalcin). Because this tight coupling is maintained in Paget disease, in the face of enormously increased skeletal turnover rates, systemic mineral homeostasis is usually unperturbed.

Genetic Forms

Approximately 20% of patients with Paget disease have a positive family history. This interesting observation plus the uncertain viral etiology has led several groups to determine the genetic loci responsible for the disease. These studies plus work done to unravel the molecular defects in patients with rare but clear disorders of accelerated and unregulated bone remodeling have shed light on molecular pathways that may be important in sporadic Paget disease.

Mutations in RANK and OPG are important in the pathogenesis of high bone remodeling states. Whyte and colleagues investigated two unrelated Navajo patients with autosomal recessive juvenile Paget disease in whom they found approximately 100-kb deletions of the gene encoding TNFRSF11B or OPG on chromosome 8q24.2. In two other clinical disorders of high bone remodeling designated as familial expansile osteolysis and expansile skeletal hyperphosphatasia, tandem duplications are present within the signal peptide of RANK, leading to a

gain-of-function in the activity of RANK. This is predicted to enhance osteoclastogenesis.

Familial Paget disease is not, however, generally explained by abnormalities in *RANK* or *OPG* genes. In contrast, several groups have uncovered mutations in SQSTM1 or sequestosome 1 (also known as p62) in multiple kindreds with Paget disease. SQSTM1 is a ubiquitin-binding protein involved in signaling pathways for IL-1, TNF, and RANKL—all molecules important in the production and function of osteoclasts. A variety of different SQSTM1 mutations are thought to explain approximately 30% of cases of familial Paget disease. The identification of additional candidate genes and their roles in bone metabolism are areas of active investigation.

Clinical Features

A. Symptoms and signs   Typical Paget disease may affect any bone, but the most common sites are the sacrum and spine (50% of patients), femur (46%), skull (28%), and pelvis (22%). The clinical features of Paget disease are pain, fractures, deformity, and manifestations of the neurologic, rheumatologic, or metabolic complications of the disease. However, at least two-thirds of patients are asymptomatic. Thus, Paget disease is often discovered as an incidental radiologic finding or during the investigation of an elevated alkaline phosphatase level. On physical examination, enlargement of the skull, frontal bossing, or deafness may be evident. Involvement of the weight-bearing long bones of the lower extremity often results in bowing. The femur and tibia bow anteriorly and laterally, but the fibula is almost never affected. Cutaneous erythema and warmth, as well as bone tenderness, may be evident over affected areas of the skeleton, reflecting greatly increased blood flow through pagetic bone. The findings of pain, warmth, and erythema led to the appellation osteitis deformans, although Paget disease is not truly an inflammatory disorder. The most common fractures in Paget disease are vertebral crush fractures and incomplete *fissure* fractures through the cortex, usually on the convex surface of the tibia or femur. Affected bones may fracture completely; when they do, healing is usually rapid and complete—the increased metabolic activity of pagetic bone seems to favor fracture healing.

B. Laboratory findings   The serum alkaline phosphatase activity is usually increased, sometimes to very high levels. Levels of biochemical markers of bone turnover are often high, but it is not clear that their determination offers any special advantage over that of serum alkaline phosphatase activity. The serum calcium and phosphate concentrations and the urinary calcium excretion are normal, although if a patient sustains a fracture and becomes immobilized, hypercalciuria and hypercalcemia may occur.

C. Imaging studies   The early stages of Paget disease are often osteolytic. Examples are erosion of the temporal bone of the skull, osteoporosis circumscripta, and pagetic lesions in the extremities, which begin in the metaphysis and migrate down

FIGURE 8–30   Lytic Paget disease in the tibia before (**left**) and after (**right**) immobilization in a cast. The lytic area has a flame- or V-shaped leading edge (**left**). (Reproduced with permission from Strewler GJ. Paget disease of bone. *West J Med*. 1984 May;140(5): 763-768.)

the shaft as a V-shaped resorptive front (Figure 8–30). Over years or even decades, the typical mixed picture of late Paget disease evolves. Trabeculae are thickened and coarse. The bone may be enlarged or bowed. In the pelvis, the iliopectineal line or pelvic brim is often thickened (Figure 8–31). In the spine, osteoblastic lesions of the vertebral bodies may present a *picture-frame* appearance or a homogeneously increased density, the *ivory vertebra*. Associated osteoarthritis may present with narrowing of the joint space (see Figure 8–31). Osteosarcoma may present with cortical destruction or a soft tissue mass (see Figure 8–31). Radionuclide bone scanning with technetium-labeled bisphosphonates or other bone-seeking agents is uniformly positive in active Paget disease and is useful for surveying the skeleton when a focus of Paget disease has been found radiographically (Figure 8–32) or the disease is suspected.

Complications

Complications of Paget disease may be neurologic, otologic, rheumatologic, neoplastic, or cardiac (Table 8–15).

A. Neurologic/Otologic   The brain, spinal cord, and peripheral nerves are all at risk.

Sensorineural deafness occurs in up to 50% of patients in whom the skull is involved, and compression of the other cranial
FIGURE 8–31   Paget disease of the right femur and pelvis. The right femur displays cortical thickening and coarse trabeculation. The right ischium is enlarged, with sclerosis of ischial and pubic rami and the right ilium. Two complications of Paget disease are present. There is concentric bilateral narrowing of the hip joint space, signifying osteoarthritis. The destructive lesion interrupting the cortex of the right ilium is an osteosarcoma. (Reproduced with permission from Strewler GJ. Paget disease of bone. *West J Med*. 1984 May;140(5): 763-768.)

nerves can also occur. At the base of the skull, Paget disease can produce platybasia and basilar impression of the brain stem, with symptoms of brain stem compression, obstructive hydrocephalus, or vertebrobasilar insufficiency. Spinal stenosis is common in vertebral Paget disease, in part because the pagetic vertebra can be

FIGURE 8–32   Bone scan of a patient with Paget disease of the pelvis, right femur, and acetabulum. Note localization of bone-seeking isotope (^{99m}Tc-labeled bisphosphonate) in these areas.

TABLE 8–15   Complications of Paget disease.

Rheumatologic Osteoarthritis Gout Calcific periarthritis
Neurologic/Otologic Basilar impression Hydrocephalus (rare) Cranial nerve dysfunction (especially deafness) Spinal cord and root compression Peripheral nerve entrapment (carpal and tarsal tunnel syndromes)
Metabolic Immobilization hypercalciuria-hypercalcemia Urolithiasis
Neoplastic Sarcoma Giant cell tumor

enlarged, and may extend posteriorly when collapse occurs, but spinal stenosis responds well to medical treatment of the disease.

B. Rheumatologic   Osteoarthritis is common in Paget disease. It may be an unrelated finding in elderly patients with the disorder, or it may result directly from pagetic deformities and their effects on wear and tear in the joints. Arthritis presents a conundrum to the clinician attempting to relieve pain, as it may be difficult to determine whether the pain originates in pagetic bone or in the nearby joint. An association of osteitis deformans and gout was first noted by James Paget himself, and asymptomatic hyperuricemia is also common.

C. Neoplastic   The most dreaded complication of Paget disease is development of a sarcoma. The tumor arises in pagetic bone, typically in individuals with polyostotic involvement, and may present with soft tissue swelling, increased pain, or a rapidly increasing alkaline phosphatase. Osteosarcoma, chondrosarcoma, and giant cell tumors all occur in Paget disease, with a combined incidence of about 1%. Because osteosarcoma is otherwise uncommon in the elderly, fully 30% of elderly patients with osteosarcoma have underlying Paget disease.

D. Cardiac   High-output congestive heart failure occurs rarely and is due to markedly increased blood flow to bone, usually in patients with more than 50% involvement of the skeleton.

Treatment

In a patient known to have Paget disease, bone pain that is unresponsive to nonsteroidal anti-inflammatory agents deserves a trial of specific therapy. As noted earlier, it may not be easy to differentiate pagetic bone pain from that due to osteoarthritis. The other indications for treatment of Paget disease are controversial. Treatment has been advocated for neurologic compression syndromes, as preparation for surgery, and to prevent deformities. Neurologic deficits often respond to medical treatment, and a trial of

treatment is often warranted. Pretreatment for 2 to 3 months before orthopedic surgery prevents excessive bleeding and postoperative hypercalcemia, but satisfactory bone healing usually occurs without medical treatment. Paget disease is sometimes treated in the hope of arresting the progress of deformities (eg, bowing of the extremities and resultant osteoarthritis), but it is not certain whether medical treatment can achieve this aim or whether it will arrest the progression of deafness in patients with skull involvement.

Two classes of agents are used in the treatment of Paget disease: bisphosphonates and CT. Both inhibit osteoclastic bone resorption.

A. Bisphosphonates The oral bisphosphonates (alendronate and risedronate) are sometimes used in the treatment of Paget disease. Alendronate is administered at a dose of 40 mg daily for 6 months. On average, alkaline phosphatase activity is suppressed by about 80% using such treatment. Biochemical remissions are often prolonged for more than 1 year, after the drug is stopped. The main side-effect is gastrointestinal upset, requiring discontinuation of therapy in about 6% of patients. Risedronate, given at a dosage of 30 mg/d for 2 months, is also highly efficacious in lowering and even normalizing alkaline phosphatase activity and reducing bone pain. For patients with gastrointestinal intolerance to oral bisphosphonates or more severe bony involvement, it may be more convenient or appropriate to administer intravenous bisphosphonates. If the disease is highly active and surgery is planned in the immediate future, intravenous therapy is generally preferred. Pamidronate, an aminobisphosphonate closely related to alendronate, has been used for this purpose. Intravenous infusions of pamidronate (60 or 90 mg) produce a high remission rate and a durable response. Preferably, intravenous zoledronic acid (5 mg) is the first-line treatment choice for efficacy because of both the strength and duration of alkaline phosphatase suppression, in patients with Paget disease. The principal side-effect observed with intravenous aminobisphosphonate administration is an acute-phase response, including fever and myalgias, that occurs in about 10% of patients and may last for several days after a dose. A very small percentage of patients receiving multiple and typically high doses of intravenous bisphosphonates can develop osteonecrosis of the jaw, although the majority of patients given intravenous zoledronic acid do not require retreatment.

B. Calcitonin Salmon CT is administered initially at a dosage of 50 to 100 IU daily until symptoms are improved; thereafter, many patients can be maintained on 50 units three times a week. Improvement in pain is usually evident within 2 to 6 weeks. On average, the alkaline phosphatase falls by 50% within 3 to 6 months. Many patients have a sustained response to treatment extending over years, and biochemical parameters are often suppressed for 6 months to 1 year after treatment is discontinued. Up to 20% of patients receiving chronic CT treatment develop late resistance to CT, which may be antibody-mediated. Data on the use of nasal spray CT's efficacy in Paget disease are limited.

BONE DISEASE IN CHRONIC KIDNEY DISEASE

Pathogenesis

Metabolism of $25(OH)D$ to $1,25(OH)_2D$ and $24,25(OH)_2D$ in the kidney is tightly regulated. CKD results in reduced circulating levels of both of these metabolites. Likely even earlier than the fall in $1,25(OH)_2D$ production that occurs in CKD is the rise in FGF23, perhaps due to phosphate retention by the diseased kidney. FGF23 rises progressively and dramatically with more advanced states of CKD. This increase contributes to the early fall in renal $1,25(OH)_2D$ production. High FGF23 levels may contribute to some of the cardiovascular complications of CKD like heart failure. Reduced $1,25(OH)_2D$ levels in progressive CKD cause intestinal calcium absorption to fall, and bone resorption appears to become less sensitive to PTH—a result that leads to hypocalcemia. Decreased phosphate excretion results in hyperphosphatemia, which amplifies the fall in serum calcium and independently increases PTH secretion. The fall in serum calcium combined with the low levels of $1,25(OH)_2D$, which is an inhibitor of PTH secretion, and the hyperphosphatemia result in hyperparathyroidism (Figure 8–33). The parathyroid glands, under chronic proliferative stimulation in uremic individuals, can develop clonal expansion of cells that harbor mutations in known parathyroid growth-promoting genes. This can result in nodular hyperplasia. In addition, the expression of both the VDR and CaSR is often depressed in tissues from individuals with chronic secondary hyperparathyroidism. Both calcium, likely acting via CaSRs, and $1,25(OH)_2D$, acting via VDRs, exert inhibitory effects on parathyroid cell growth.

The net effect of deficient $1,25(OH)_2D$ and $24,25(OH)_2D$ and excess PTH and FGF23 on bone in CKD is complex. Bone
FIGURE 8–33 Pathogenesis of renal secondary hyperparathyroidism.

may show osteitis fibrosa cystica (reflecting excessive PTH), osteomalacia (in part reflecting decreased vitamin D metabolites and high FGF23 which have complex effects on bone mineralization), or a combination of the two. One particularly debilitating skeletal complication is low turnover or adynamic bone disease, now found in an increasing percentage of patients on hemodialysis. In the past but rarely now, some patients had increased aluminum content in their bones, particularly in the region where mineralization is occurring (calcification front), and this appeared to inhibit mineralization. More commonly, however, these patients do not have aluminum excess or increased osteoid but just have low bone turnover for reasons that are not entirely clear, although low levels of PTH have been implicated. Such patients are particularly prone to develop symptoms of bone pain, fractures, and muscle weakness, and are particularly sensitive to developing hypercalcemia when treated with calcitriol despite the relatively low levels of PTH. The combined picture of disordered bone and mineral metabolism and the pathologic vascular calcification in renal disease has been termed CKD-mineral bone disease (CKD-MBD).

Clinical Features

Most patients with advanced stages of CKD have osteitis fibrosa alone or in combination with osteomalacia. If not well controlled, these patients will have a low serum level of calcium and high serum levels of phosphorus, alkaline phosphatase, and PTH. A few patients develop severe secondary hyperparathyroidism in which the PTH level increases dramatically and stays elevated even with restoration of the serum calcium to normal. Such patients are prone to developing hypercalcemia with the usual replacement doses of calcium (sometimes referred to as tertiary hyperparathyroidism). As noted earlier another subset of patients with CKD present with relatively normal levels of PTH and alkaline phosphatase. Their serum calcium levels are often elevated after treatment with small doses of calcitriol. These patients generally have adynamic bone disease on bone biopsy.

Treatment

Patients with renal bone disease generally respond to calcitriol (0.5-1 µg/d) or one of the vitamin D analogs paricalcitol [19-nor-1-alpha, $25(OH)_2D_2$] or doxercalciferol ($1\alpha OHD_2$), calcium supplementation (1-2 g/d), and phosphate restriction. Vitamin D supplementation is also recommended to ensure adequate $25(OH)$D levels (30 ng/mL). To avoid aluminum intoxication, sevelamer (Renagel), lanthanum carbonate (Fosrenol), and other nonaluminum phosphate binders are used to reduce intestinal phosphate absorption. To minimize the calcium-phosphate product, absorbable calcium-containing salts are used only at low doses to maintain sufficient calcium intake and not to act as a phosphate binder. The goal is to maintain normal serum levels of calcium, phosphate, and alkaline phosphatase. This regimen treats osteitis fibrosa more effectively than osteomalacia.

To prevent the development of adynamic bone disease, intact PTH levels higher than the upper limit of normal in standard intact PTH assays are encouraged. The optimal intact PTH level

for preserving skeletal integrity in end-stage renal disease (ESRD) and in patients on dialysis is uncertain. Newer or so-called biointact or whole PTH assays give a better reflection of the levels of the full-length PTH(1-84) molecule in these settings (described earlier). Patients with aluminum intoxication are very sensitive to and respond poorly to calcitriol and calcium, with rapid onset of hypercalcemia and little improvement in their bone disease. These patients may respond to chelation therapy with deferoxamine, a drug also used for iron chelation.

Severe secondary hyperparathyroidism is difficult to manage. These patients are prone to the development of hypercalcemia with calcium supplementation. Intravenous doses of calcitriol with hemodialysis may preferentially inhibit PTH secretion with less effect on raising serum calcium than when given orally. Several analogs of calcitriol with less hypercalcemic potential than calcitriol itself are approved for the management of such patients.

A major advance in the treatment of uremic secondary hyperparathyroidism is the use of the calcimimetic cinacalcet. This agent directly inhibits PTH secretion by activating the CaSR on parathyroid cells. Cinacalcet lowers levels of PTH and presumably of bone turnover and has less of a tendency to elevate the calcium-phosphate product, unlike the vitamin D analogs, which tend to raise serum calcium and phosphate. Cinacalcet has contributed substantially to the medical management of uremic secondary hyperparathyroidism and has markedly reduced the need for subtotal parathyroidectomy to treat refractory secondary or tertiary hyperparathyroidism in patients with CKD. The major side-effects of cinacalcet, nausea and vomiting, limit its use in some patients.

HEREDITARY FORMS OF HYPERPHOSPHATEMIA

Tumoral Calcinosis

Mutations in genes leading to reduced FGF23 production, secretion, or action have recently been described which result in hyperphosphatemia and increased $1,25(OH)_2D$ production. FGF23 requires glycosylation for its export from the cell where it is produced. Although FGF23 utilizes FGF receptors in common with many other members of the FGF family (FGFR 1 and 3), it also requires a coreceptor **alpha klotho**, to activate FGF23-mediated signaling in target cells. Inactivating mutations in FGF23 itself, the enzyme that glycosylates FGF23 which is necessary for secretion, **GALNT3** (UDP-N-acetyl-α-D-galactosamine transferase), and alpha klotho all lead to hyperphosphatemia and increased $1,25(OH)_2D$ levels, although serum calcium levels are generally normal. Urinary phosphate reabsorption is increased. These findings are the opposite of those of familial hypophosphatemic disorders described earlier. As a result of the increased calcium-phosphate product, ectopic calcification occurs, generally around joints and soft tissues. Dentition may be affected in some individuals. Treatment involves the use of phosphate binders in an effort to reduce the serum phosphate levels and reduce the painful and sometimes disfiguring ectopic calcifications which can become very large.

Glucocorticoids and Adrenal Androgens

Ty B. Carroll, MD, David C. Aron, MD, MS,
James W. Findling, MD, and J. Blake Tyrrell, MD

ACTH	Adrenocorticotropic hormone	HSD	Hydroxysteroid dehydrogenase
ADH	Antidiuretic hormone (vasopressin)	HSP	Heat shock protein
AIRE	Autoimmune regulator gene	ICMA	Immunochemiluminometric assay
APS	Autoimmune polyendocrine syndrome	IL	Interleukin
ARMC5	Armadillo-repeat containing 5	IPSS	Inferior petrosal sinus sampling
AVP	Arginine vasopressin	IRMA	Immunoradiometric assay
BMAH	Bilateral macronodular adrenal hyperplasia	LC/MS/MS	Liquid chromatography tandem mass spectroscopy
CBG	Corticosteroid-binding globulin	LH	Luteinizing hormone
CRH	Corticotropin-releasing hormone	PMN	Polymorphonuclear neutrophil
DAX1	Dosage-sensitive sex reversal-adrenal hypoplasia gene product	PRA	Plasma renin activity
DHEA	Dehydroepiandrosterone	PRKACA	Protein kinase A catalytic subunit
DOC	Deoxycorticosterone	PRL	Prolactin
ELISA	Enzyme-linked immunosorbent assay	PTH	Parathyroid hormone
GH	Growth hormone	RANK	Receptor activator of nuclear factor kappa B
GIP	Glucose-dependent insulinotropic peptide/ Gastrointestinal inhibitory polypeptide	SF-1	Steroidogenic factor-1a
GnRH	Gonadotropin-releasing hormone	SHBG	Sex hormone–binding globulin
HLA	Human leukocyte antigen	StAR	Steroidogenic acute regulatory protein
HPA	Hypothalamic-pituitary-adrenal	TRH	Thyrotropin-releasing hormone
HPLC	High-performance liquid chromatography	TSH	Thyroid-stimulating hormone (thyrotropin)
		VLCFA	Very long chain fatty acid

The adrenal cortex produces many steroid hormones of which the most important are cortisol, aldosterone, and the adrenal androgens. Disorders of the adrenal glands lead to classic endocrinopathies such as Cushing syndrome, Addison disease, hyperaldosteronism, and the syndromes of congenital adrenal hyperplasia. This chapter describes the physiology and disorders of the glucocorticoids and the adrenal androgens. Disorders of aldosterone secretion are discussed in Chapter 10 and congenital defects in adrenal hormone biosynthesis in Chapters 10 and 14.

Hirsutism and virilization (which reflect excess androgen action) are discussed in Chapter 13.

Advances in diagnostic procedures have simplified the evaluation of adrenocortical disorders; in particular, the assay of plasma glucocorticoids, androgens, and adrenocorticotropin (ACTH) has allowed more rapid and precise diagnosis. Recent discoveries have also begun to elucidate the genetic basis for many disorders of the adrenal cortex, and advances in surgical and medical treatment have improved the outlook for patients with these disorders.

EMBRYOLOGY AND ANATOMY

Embryology

The adrenal cortex is of mesodermal origin and derives from a single cell lineage characterized by expression of certain transcription factors such as steroidogenic factor-1 (SF-1). At 2 months' gestation, the cortex, already identifiable as a separate organ, is composed of a fetal zone and a definitive zone similar to the adult adrenal cortex. The adrenal cortex then increases rapidly in size; at mid gestation, it is considerably larger than the kidney and much larger than the adult gland in relation to total body mass. The fetal zone makes up the bulk of the weight of the adrenal cortex at this time. Several genes encoding transcription factors are important in adrenal development and differentiation. These include SF-1 and the product of the dosage-sensitive sex reversal–adrenal hypoplasia gene (*DAX1*), among others; mutations of the *DAX1* gene are associated with congenital adrenal hypoplasia.

The fetal adrenal is under the control of ACTH by mid pregnancy, but the fetal zone is deficient in the activity of 3β-hydroxysteroid dehydrogenase (see section on Biosynthesis of Cortisol and Adrenal Androgens, later) and thus produces mainly dehydroepiandrosterone (DHEA) and DHEA sulfate, which serve as precursors of maternal-placental estrogen production after conversion in the liver to 16α-hydroxylated derivatives. The definitive zone synthesizes a number of steroids and is the major site of fetal cortisol synthesis.

Anatomy

The anatomic relationship of the fetal and definitive zones is maintained until birth, at which time the fetal zone gradually disappears, with a consequent decrease in adrenocortical weight in the 3 months following delivery. During the next 3 years, the adult adrenal cortex develops from cells of the outer layer of the cortex and differentiates into the three adult zones: glomerulosa, fasciculata, and reticularis–adrenal zonation.

The adult adrenal glands, with a combined weight of 8 to 10 g, lie in the retroperitoneum above or medial to the upper poles of the kidneys (Figure 9–1). A fibrous capsule surrounds the gland; the cortex comprises 90% of the adrenal weight, the inner medulla is about 10%.

The adrenal cortex is richly vascularized and receives its main arterial supply from branches of the inferior phrenic artery, the renal arteries, and the aorta. These small arteries form an arterial plexus beneath the capsule and then enter a sinusoidal system that penetrates the cortex and medulla, draining into a single central vein in each gland. The right adrenal vein drains directly into the posterior aspect of the vena cava; the left adrenal vein enters the left renal vein. These anatomic features account for the clinically important fact that it is relatively easier to catheterize the left adrenal vein than it is to catheterize the right adrenal vein.

Microscopic Anatomy

Histologically, the adult cortex is composed of three zones: an outer zona glomerulosa, a zona fasciculata, and an inner zona reticularis (Figure 9–2). However, the inner two zones appear to function as a unit (see later). The zona glomerulosa, which produces aldosterone and constitutes about 15% of adult cortical volume, is deficient in 17α-hydroxylase activity and thus cannot produce cortisol or androgens (see later and Chapter 10). The zona glomerulosa lacks a well-defined structure, and the small lipid-poor cells are scattered beneath the adrenal capsule.
FIGURE 9–1 Location and blood supply of the adrenal glands (schematic). (Reproduced with permission from Felig P, et al, eds. *Endocrinology and Metabolism*, 4th ed. New York: McGraw-Hill Education; 2002.)
FIGURE 9–2 Zones of the adrenal cortex and medulla. Each of the zones of the cortex (reticularis, fasciculata, and glomerulosa) is derived from different embryologic origins, and their cells have varying hormonal productive capabilities. (Reproduced with permission from Widmaier EP, Raff HR, Strang KT. *Vander's Human Physiology: The Mechanisms of Body Function*. 11th ed. New York: McGraw-Hill Education; 2008.)

The zona fasciculata is the thickest layer of the adrenal cortex, making up about 75% of the cortex, and produces cortisol and androgens. The cells of the zona fasciculata are larger and contain more lipids and thus are termed **clear cells**. These cells extend in columns from the narrow zona reticularis to either the zona glomerulosa or to the capsule. The inner zona reticularis surrounds the medulla and also produces cortisol and androgens. The compact cells of this narrow zone lack significant lipid content but do contain lipofuscin granules. The zonae fasciculata and reticularis are regulated by ACTH; excess or deficiency of this hormone alters their structure and function. Thus, both zones atrophy when ACTH is deficient; when ACTH is present in excess, hyperplasia and hypertrophy of these zones occur. In addition, chronic stimulation with ACTH leads to a gradual depletion of the lipid from the clear cells of the zona fasciculata at the junction of the two zones; these cells thus attain the characteristic appearance of the compact reticularis cells. With chronic excessive stimulation, the compact reticularis cells extend outward and may reach the outer capsule. It is postulated that the zona fasciculata cells can respond acutely to ACTH stimulation with increased cortisol production, whereas the reticularis cells maintain basal glucocorticoid secretion and that induced by prolonged ACTH stimulation.

BIOSYNTHESIS OF CORTISOL AND ADRENAL ANDROGENS

Steroidogenesis

The major hormones secreted by the adrenal cortex are cortisol, the androgens, and aldosterone. The carbon atoms in the steroid molecule are numbered as shown in Figure 9–3, and the major biosynthetic pathways and hormonal intermediates are illustrated in Figure 9–4.

The scheme of adrenal steroidogenic synthesis has been clarified by analysis of the steroidogenic enzymes. Most of these enzymes belong to the family of cytochrome P450 oxygenases (see Table 9–1 for current and historical nomenclature conventions). In mitochondria, the *CYP11A* gene, located on chromosome 15, encodes P450scc, the enzyme responsible for cholesterol side chain cleavage. *CYP11B1*, a gene located on chromosome 8, encodes P450c11, another mitochondrial enzyme, which mediates 11β-hydroxylation in the zona reticularis and zona fasciculata. This reaction converts 11-deoxycortisol to cortisol and 11-deoxycorticosterone (11-DOC) to corticosterone. In the zona glomerulosa, *CYP11B2*, also located on chromosome 8, encodes the enzyme P450aldo, also known as aldosterone synthase.
FIGURE 9–3 Structure of adrenocortical steroids. The letters in the formula for progesterone identify the A, B, C, and D rings; the numbers show the positions in the basic C_{21} steroid structure. The angular methyl groups (positions 18 and 19) are usually indicated simply by straight lines, as in the lower formula. Dehydroepiandrosterone is a 17-ketosteroid formed by cleavage of the side chain of the C_{21} steroid 17-hydroxypregnenolone and its replacement by an O atom. (Reproduced with permission from Ganong WF. *Review of Medical Physiology*. 14th ed. McGraw-Hill; 1989.)

P450aldo mediates 11β-hydroxylation, 18-hydroxylation, and 18-oxidation to convert 11-DOC to corticosterone, 18-hydroxycorticosterone, and aldosterone, respectively. In the endoplasmic reticulum, gene *CYP17*, located on chromosome 10, encodes a single enzyme, P450c17, which mediates both 17α-hydroxylase activity and 17,20-lyase activity, and the gene *CYP21A2* encodes the P450c21, which mediates 21-hydroxylation of both progesterone and 17-hydroxyprogesterone. The 3β-hydroxysteroid dehydrogenase: $\Delta^{5,4}$-isomerase activities are mediated by a single non-P450 microsomal enzyme (see Figure 9–4).

A. Zones and steroidogenesis Because of enzymatic differences between the zona glomerulosa and the inner two zones, the adrenal cortex functions as two separate units, with differing regulation and secretory products. Thus, the zona glomerulosa, which produces aldosterone, lacks 17α-hydroxylase activity and cannot synthesize 17α-hydroxypregnenolone and 17α-hydroxyprogesterone, which are the precursors of cortisol and the adrenal androgens. The synthesis of aldosterone by this zone is primarily regulated by the renin-angiotensin system and by potassium (see Chapter 10).

The zona fasciculata and zona reticularis (see Figure 9–4) produce cortisol, androgens, and small amounts of estrogens. These zones, primarily regulated by ACTH, do not express the gene *CYP11B2* (encoding P450aldo) and therefore cannot convert 11-DOC to aldosterone (see Chapter 10).
FIGURE 9–4 Steroid biosynthesis in the zona fasciculata and zona reticularis of the adrenal cortex. The major secretory products are underlined. The enzymes for the reactions are numbered on the left and at the top of the chart, with the steps catalyzed shown by the shaded bars. ① P450scc, cholesterol 20,22-hydroxylase:20,22 desmolase activity; ② 3βHSD/ISOM, 3-hydroxysteroid dehydrogenase; δ⁵-oxosteroid isomerase activity; ③ P450c21, 21α-hydroxylase activity; ④ P450c11, 11β-hydroxylase activity; ⑤ P450c17, 17α-hydroxylase activity; ⑥ P450c17, 17,20-lyase/desmolase activity; ⑦ sulfokinase. (Modified with permission from Ganong WF. *Review of Medical Physiology*. 16th ed. McGraw-Hill; 1993.)

TABLE 9–1   The main components of the steroidogenic pathway.

Enzyme	Gene	Chromosomal Location	Enzyme Activity (or Activities)	Subcellular Localization	Characteristic Features of Normal Tissue-Specific Expression
Steroidogenic acute regulatory protein (StAR)	StAR	8p11.2	Activation of peripheral type benzodiazepine receptor	Outer mitochondrial membrane	All steroid hormone–producing cells except the placenta, Schwann cells, and the brain
Peripheral type benzodiazepine receptor	PDA	22q13.31	Regulated cholesterol channel	Forms channel at the contact sites between the outer and inner mitochondrial membranes	All steroid hormone–producing cells
P450scc	CYP11A	15q23-24	Cholesterol-20,22-desmolase	Matrix side of inner mitochondrial membrane	All steroid hormone–producing cells
3β-Hydroxysteroid dehydrogenase (HSD)/isomerase	3β-Hydroxysteroid dehydrogenase type 1	1p13, the HSD3B1 and HSD3B2 loci are located 1-2 cm from the centromeric marker D1Z5	3β-Hydroxysteroid dehydrogenase	Smooth endoplasmic reticulum	Expressed in syncytiotrophoblast cells, sebaceous glands
	3β-Hydroxysteroid dehydrogenase type 2				Expressed in the definitive adrenal cortex and the gonads. Absent from the fetal zone of the adrenal cortex
P450c21	CYP21B	6p21.3 (close to HLA locus)	21-hydroxylase	Smooth endoplasmic reticulum	Only in adrenal cortex (all zones); low levels in fetal zone
	CYP21A	6p21.3 (close to HLA locus)	Pseudogene	N/A	N/A
P450c11	CYP11B1	8q21-22	11β-hydroxylase	Matrix side of inner mitochondrial membrane	Only expressed in zona fasciculata and zona reticularis of the adrenal cortex; low levels in fetal zone
P450aldo	CYP11B2	8q24.3	Aldosterone synthase: 11β-hydroxylase, 18-hydroxylase, 18-oxidase	Matrix side of inner mitochondrial membrane	Only expressed in the zona glomerulosa of the adrenal cortex; low levels in fetal zone
P450c17	CYP17	10q24-25	17α-hydroxylase, 17,20-lyase	Smooth endoplasmic reticulum	Absent from the zona glomerulosa in adults, the placenta, and the definitive zone of fetal adrenal cortex until the third trimester
P450arom	CYP19	15q	Aromatase	Smooth endoplasmic reticulum	Expressed in numerous tissues including gonads, brain, adrenal, adipose tissue, and bone

Modified with permission from Kacsoh B. *Endocrine Physiology*. New York: McGraw-Hill Education; 2000.

B. Cholesterol uptake and synthesis   Synthesis of cortisol and the androgens by the zonae fasciculata and reticularis begins with cholesterol, as does the synthesis of all steroid hormones. Plasma lipoproteins are the major source of adrenal cholesterol, although synthesis within the gland from acetate also occurs. Low-density lipoprotein accounts for about 80% of cholesterol delivered to the adrenal gland. A small pool of free cholesterol within the adrenal is available for rapid synthesis of steroids when the adrenal is stimulated. When stimulation occurs, there is also increased hydrolysis of stored cholesteryl esters to free cholesterol, increased uptake from plasma lipoproteins, and increased cholesterol synthesis within the gland. The acute

response to a steroidogenic stimulus is mediated by the steroidogenic acute regulatory protein (StAR). This mitochondrial phosphoprotein enhances cholesterol transport from the outer to the inner mitochondrial membrane. Mutations in the *StAR* gene result in congenital lipoid adrenal hyperplasia with severe cortisol and aldosterone deficiencies at birth.

C. Cholesterol metabolism   The conversion of cholesterol to pregnenolone is the rate-limiting step in adrenal steroidogenesis and the major site of ACTH action in the adrenal. This step occurs in the mitochondria and involves two hydroxylations and then the side chain cleavage of cholesterol. A single enzyme, CYP11A, mediates this process; each step requires molecular oxygen and a pair of electrons. The latter are donated by nicotinamide adenine dinucleotide phosphate (NADPH) to adrenodoxin reductase (ferredoxin reductase), a flavoprotein, and then to adrenodoxin, an iron-sulfur protein, and finally to CYP11A. Both adrenodoxin reductase and adrenodoxin are also involved in the action of CYP11B1 (see earlier). Electron transport to microsomal cytochrome P450 involves P450 reductase, a flavoprotein distinct from adrenodoxin reductase. Pregnenolone is then transported outside the mitochondria before further steroid synthesis occurs.

D. Synthesis of cortisol   Cortisol synthesis proceeds by 17α-hydroxylation of pregnenolone by CYP17 within the smooth endoplasmic reticulum to form 17α-hydroxypregnenolone. This steroid is then converted to 17α-hydroxyprogesterone after conversion of its 5,6 double bond to a 4,5 double bond by the 3β-hydroxysteroid dehydrogenase: $\Delta^{5,4}$-oxosteroid isomerase enzyme complex, which is also located within the smooth endoplasmic reticulum. An alternative but apparently less important pathway in the zonae fasciculata and reticularis is from pregnenolone to progesterone to 17α-hydroxyprogesterone (see Figure 9–4).

The next step, which is again microsomal, involves the 21-hydroxylation by CYP21A2 of 17α-hydroxyprogesterone to form 11-deoxycortisol; this compound is further hydroxylated within mitochondria by 11β-hydroxylation (CYP11B1) to form cortisol. The zona fasciculata and zona reticularis also produce 11-DOC, 18-hydroxydeoxycorticosterone, and corticosterone. However, as noted earlier, the absence of the mitochondrial enzyme CYP11B2 prevents production of aldosterone by these zones of the adrenal cortex. Cortisol secretion under basal (ie, nonstressed) conditions ranges from 8 to 25 mg/d (22-69 μmol/d), with a mean of about 9.2 mg/d (25 μmol/d)—rates lower than most previous calculations.

E. Synthesis of androgens   The production of adrenal androgens from pregnenolone and progesterone requires prior 17α-hydroxylation (CYP17) and thus does not occur in the zona glomerulosa. The major quantitative production of androgens is by conversion of 17α-hydroxypregnenolone to the 19-carbon compounds (C-19 steroids) DHEA and its sulfate conjugate DHEA sulfate. Thus, 17α-hydroxypregnenolone

undergoes removal of its two-carbon side chain at the C_{17} position by microsomal 17,20-desmolase (CYP17), yielding DHEA with a keto group at C_{17}. DHEA is then converted to DHEA sulfate by a reversible adrenal sulfokinase. The other major adrenal androgen, androstenedione, is produced mostly from DHEA, mediated by CYP17, and possibly from 17α-hydroxyprogesterone, also by CYP17. Androstenedione can be converted to testosterone, although adrenal secretion of this hormone is minimal. The adrenal androgens, DHEA, DHEA sulfate, and androstenedione, have minimal intrinsic androgenic activity, and they contribute to androgenicity by their peripheral conversion to the more potent androgens testosterone and dihydrotestosterone. Although DHEA and DHEA sulfate are secreted in greater quantities, androstenedione is qualitatively more important, because it is more readily converted peripherally to testosterone (see Chapter 12). Of note, studies have identified *de novo* synthesis of some steroid hormones in nerve and cardiac tissues, where they appear to act as paracrine or autocrine factors. Steroidogenic enzymes (eg, 3β-hydroxysteroid dehydrogenase and aromatase) are expressed in many tissues.

Regulation of Secretion

A. Secretion of CRH and ACTH   ACTH is the trophic hormone of the zonae fasciculata and reticularis and the major regulator of cortisol and adrenal androgen production, although other factors produced within the adrenal, including neurotransmitters, neuropeptides, and nitric oxide also play a role. ACTH in turn is regulated by the hypothalamus and central nervous system via neurotransmitters and corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP). The neuroendocrine control of CRH and ACTH secretion involves three mechanisms (see later and Chapter 4).

B. ACTH effects on the adrenal cortex   ACTH administration leads to the rapid synthesis and secretion of steroids; plasma levels of these hormones rise within minutes. ACTH increases RNA, DNA, and protein synthesis. Chronic stimulation leads to adrenocortical hyperplasia and hypertrophy; conversely, ACTH deficiency results in decreased steroidogenesis and is accompanied by adrenocortical atrophy, decreased gland weight, and decreased protein and nucleic acid content.

C. ACTH and steroidogenesis   ACTH binds to high-affinity plasma membrane receptors, thereby activating adenylyl cyclase and increasing cyclic adenosine monophosphate, which in turn activates intracellular phosphoprotein kinases (Figure 9–5), including StAR. Mutations of the ACTH receptor (also known as the *melanocortin-2 receptor*) gene are associated with familial glucocorticoid deficiency. ACTH action results in increased free cholesterol formation as a consequence of increased cholesterol esterase activity and decreased cholesteryl ester synthetase as well as increased lipoprotein uptake by the adrenal cortex. This process stimulates the rate-limiting
FIGURE 9–5 Mechanism of action of ACTH on cortisol-secreting cells in the inner two zones of the adrenal cortex. When ACTH binds to its receptor (R), adenylyl cyclase (AC) is activated via G_s. The resulting increase in cAMP activates protein kinase A, and the kinase phosphorylates cholesteryl ester hydrolase (CEH), increasing its activity. Consequently, more free cholesterol is formed and converted to pregnenolone in the mitochondria. Note that in the subsequent steps in steroid biosynthesis, products are shuttled between the mitochondria and the smooth endoplasmic reticulum (SER). (Reproduced with permission from Ganong WF. *Review of Medical Physiology*. 16th ed. McGraw-Hill; 1993.)

step—cholesterol delivery to the side chain cleavage enzyme (P450scc or CYP11A1) for conversion to Δ^5-pregnenolone, thereby initiating steroidogenesis.

D. Neuroendocrine control Cortisol secretion is closely regulated by ACTH, and plasma cortisol levels parallel those of ACTH (Figure 9–6). There are three mechanisms of neuroendocrine control: (1) episodic secretion and the circadian rhythm of
FIGURE 9–6 Fluctuations in plasma ACTH and glucocorticoids (11-OHCS) throughout the day. Note the greater ACTH and glucocorticoid rises in the morning before awakening. (Reproduced with permission from Krieger DT et al. Characterization of the normal temporal pattern of corticosteroid levels. *J Clin Endocrinol Metab*. 1971 Feb;32(2):266-284.)

ACTH, (2) stress responsiveness of the hypothalamic-pituitary-adrenal (HPA) axis, and (3) feedback inhibition by cortisol of ACTH secretion.

1. **Circadian rhythm**—Circadian rhythm is superimposed on episodic secretion; it is the result of central nervous system events that regulate both the number and magnitude of CRH and ACTH secretory episodes. Cortisol secretion is low in the late evening and continues to decline in the first several hours of sleep, at which time plasma cortisol levels may be nearly undetectable. During the third and fifth hours of sleep there is an increase in secretion; but the major secretory episodes begin in the sixth to eighth hours of sleep (see Figure 9–6) and then begin to decline as wakefulness occurs. About half of the total daily cortisol output is secreted during this period. Cortisol secretion then gradually declines during the day, with fewer secretory episodes of decreased magnitude; however, there is increased cortisol secretion in response to eating and exercise.

    Although this general pattern is consistent, there is considerable intra- and inter-individual variability, and the circadian rhythm may be altered by changes in sleep pattern, light-dark exposure, and feeding times. The rhythm is also changed by (1) physical stresses such as major illness, surgery, trauma, or starvation; (2) psychologic stress, including severe anxiety, endogenous depression, and the manic phase of manic-depressive psychosis; (3) central nervous system and pituitary disorders; (4) Cushing syndrome; (5) liver disease and other conditions that affect cortisol metabolism; (6) chronic renal failure; and (7) alcoholism. Cyproheptadine inhibits the circadian rhythm, possibly by its antiserotonergic effects, whereas other drugs usually have no effect.

2. **Stress responsiveness**—Plasma ACTH and cortisol secretion are also characteristically responsive to physical stress. Thus, plasma ACTH and cortisol are secreted within minutes following the onset of stresses such as surgery and hypoglycemia, and these responses abolish circadian periodicity if the stress is prolonged. Stress responses originate in the central nervous system and increase hypothalamic CRH and thus pituitary ACTH secretion. Stress responsiveness of plasma ACTH and cortisol is abolished by prior high-dose glucocorticoid administration and in spontaneous Cushing syndrome; conversely, the responsiveness of ACTH secretion is enhanced following adrenalectomy. Regulation of the HPA axis is linked to that of the immune system. For example, interleukin-1 (IL-1) stimulates ACTH secretion, and cortisol inhibits IL-1 synthesis.

3. **Feedback inhibition**—The third major regulator of ACTH and cortisol secretion is that of feedback inhibition by glucocorticoids of CRH, ACTH, and cortisol secretion. Glucocorticoid feedback inhibition occurs at both the pituitary and hypothalamus and involves two distinct mechanisms—fast and delayed feedback inhibition.

    Fast feedback inhibition of ACTH secretion is rate-dependent; that is, it depends on the rate of increase of the glucocorticoid but not the dose administered. This phase is rapid (within minutes) and transient (lasting <10 minutes), suggesting mediation by a noncytosolic glucocorticoid receptor mechanism. **Delayed feedback inhibition** is both time- and dose-dependent. With continued glucocorticoid administration, ACTH levels continue to decrease and become unresponsive to stimulation, ultimately resulting in suppression of CRH and ACTH release and

atrophy of the zonae fasciculata and reticularis. The suppressed HPA axis fails to respond to stress and stimulation. Delayed feedback appears to act via the classic glucocorticoid receptor mechanism (see later).

E. ACTH effects on regulation of androgen production Adrenal androgen production in adults is also regulated by ACTH; both DHEA and androstenedione exhibit circadian periodicity in concert with ACTH and cortisol. In addition, plasma concentrations of DHEA and androstenedione increase rapidly with ACTH administration and are suppressed by glucocorticoid administration. DHEA sulfate, because of its slow metabolic clearance rate, does not exhibit a diurnal rhythm. The existence of a separate anterior pituitary hormone that regulates adrenal androgen secretion has long been postulated but not yet proved.

CIRCULATION OF CORTISOL AND ADRENAL ANDROGENS

Cortisol and the adrenal androgens circulate bound to plasma proteins. The plasma half-life of cortisol (60-90 minutes) is determined by the extent of plasma binding and by the rate of metabolic inactivation.

Plasma-Binding Proteins

Cortisol and adrenal androgens are secreted in an unbound state; however, these hormones bind to plasma proteins on entering the circulation. Cortisol binds mainly to corticosteroid-binding globulin (CBG, transcortin) and to a lesser extent to albumin, whereas the androgens bind chiefly to albumin. Bound steroids are biologically inactive; the unbound or free fraction is active. The plasma proteins may provide a pool of circulating cortisol by delaying metabolic clearance, thus preventing more marked fluctuations of plasma-free cortisol levels during episodic secretion by the gland. Because there are no binding proteins in saliva, salivary cortisol reflects free cortisol.

Free and Bound Cortisol

Under basal conditions, about 10% of the circulating cortisol is free, about 75% is bound to CBG, and the remainder is bound to albumin. The plasma free cortisol level is approximately 1 µg/dL, and it is this biologically active cortisol that is regulated by ACTH.

A. Corticosteroid-binding globulin Corticosteroid-binding globulin (CBG) has a molecular weight of about 50,000, is produced by the liver, and binds cortisol with high affinity. The CBG in plasma has a cortisol-binding capacity of about 25 µg/dL. When total plasma cortisol concentrations rise above this level, the free concentration rapidly increases and exceeds its usual fraction of 10% of the total cortisol. Other endogenous steroids usually do not appreciably affect cortisol binding to CBG; an exception is in late pregnancy, when progesterone may occupy

about 25% of the binding sites on CBG. Synthetic steroids do not bind significantly to CBG—with the exception of prednisolone. CBG levels are increased in high-estrogen states (pregnancy; estrogen or oral contraceptive use), hyperthyroidism, diabetes, certain hematologic disorders, and on a genetic basis. CBG concentrations are decreased in familial CBG deficiency, hypothyroidism, and protein deficiency states such as severe liver disease or nephrotic syndrome.

B. Albumin Albumin has a much greater capacity for cortisol binding but a lower affinity. It normally binds about 15% of the circulating cortisol, and this proportion increases when the total cortisol concentration exceeds the CBG-binding capacity. Synthetic glucocorticoids are extensively bound to albumin (eg, about 75% of dexamethasone in plasma is bound to albumin).

C. Androgen binding Androstenedione, DHEA, and DHEA sulfate circulate weakly bound to albumin. However, testosterone is bound extensively to a specific globulin, sex hormone–binding globulin (SHBG) (see Chapter 12).

METABOLISM OF CORTISOL AND ADRENAL ANDROGENS

The metabolism of these steroids renders them inactive and increases their water solubility, as does their subsequent conjugation with glucuronide or sulfate groups. These inactive, conjugated metabolites are more readily excreted by the kidney. The liver is the major site of steroid catabolism and conjugation, and 90% of these metabolized steroids are excreted by the kidney.

Conversion and Excretion of Cortisol

Cortisol is modified extensively before excretion in urine; less than 1% of secreted cortisol appears in the urine unchanged.

A. Hepatic conversion Hepatic metabolism of cortisol involves a number of metabolic conversions of which the most important (quantitatively) is the irreversible inactivation of the steroid by Δ^4-reductases, which reduce the 4,5 double bond of the A ring. Dihydrocortisol, the product of this reaction, is then converted to tetrahydrocortisol by a 3-hydroxysteroid dehydrogenase. Cortisol is also converted extensively by 11β-hydroxysteroid dehydrogenase to the biologically inactive cortisone, which is then metabolized by the enzymes described earlier to yield tetrahydrocortisone. Tetrahydrocortisol and tetrahydrocortisone can be further altered to form the cortoic acids. These conversions result in the excretion of approximately equal amounts of cortisol and cortisone metabolites. Cortisol and cortisone are also metabolized to the cortols and cortolones and to a lesser extent by other pathways (eg, to 6β-hydroxycortisol).

B. Hepatic conjugation More than 95% of cortisol and cortisone metabolites are conjugated by the liver and then

reenter the circulation to be excreted in the urine. Conjugation is mainly with glucuronic acid at the 3α-hydroxyl position.

C. Variations in clearance and metabolism

The metabolism of cortisol is altered by a number of circumstances. It is decreased in infants and in the elderly. It is impaired in chronic liver disease, leading to decreased renal excretion of cortisol metabolites; however, the plasma cortisol level remains normal. Hypothyroidism decreases both metabolism and excretion; conversely, hyperthyroidism accelerates these processes. Cortisol clearance may be reduced in starvation and anorexia nervosa and is also decreased in pregnancy because of the elevated CBG levels. The metabolism of cortisol to 6β-hydroxycortisol is increased in the neonate, in pregnancy, with estrogen therapy, and in patients with liver disease or severe chronic illness. Cortisol metabolism by this pathway is also increased by drugs that induce hepatic microsomal enzymes, including barbiturates, phenytoin, mitotane, aminoglutethimide, and rifampin. These alterations generally are of minor physiologic importance as the free cortisol levels remain relatively stable in these conditions. However, they result in decreased excretion of the urinary metabolites of cortisol measured as 17-hydroxycorticosteroids. These conditions and drugs have a greater influence on the metabolism of synthetic glucocorticoids and may result in

inadequate plasma levels of the administered glucocorticoid because of rapid clearance and metabolism.

D. Cortisol-cortisone shunt

Aldosterone is the principal mineralocorticoid controlling sodium and potassium exchange in the distal nephron. Mineralocorticoid receptors in the kidney are responsible for this effect, and the sensitivities of both the glucocorticoid receptor and the mineralocorticoid receptor for cortisol *in vitro* are similar. Small changes in aldosterone affect sodium and potassium exchange in the kidney, whereas free and biologically active cortisol does not, yet cortisol circulates in much higher concentrations. This apparent paradox is explained by an intracellular enzyme—11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2)—that metabolizes cortisol to inactive cortisone and protects the mineralocorticoid receptor from cortisol binding (Figure 9–7). However, when circulating cortisol is extremely high (as in severe Cushing syndrome), this prereceptor metabolism of cortisol is overwhelmed and the mineralocorticoid receptor is activated by cortisol, resulting in volume expansion, hypertension, and hypokalemia. The active ingredient of licorice (glycyrrhizic acid) actually inhibits 11β-HSD2 and gives cortisol free access to the unprotected mineralocorticoid receptor in the kidney, causing hypokalemia and hypertension. In addition, some tissues can actually convert the inactive
FIGURE 9–7 Cortisol-cortisone shunt. Contrasting functions of the isozymes of 11β-HSD. 11β-HSD2 is an exclusive 11β-dehydrogenase that acts in classical aldosterone target tissues to exclude cortisol from otherwise nonselective mineralocorticoid receptors. Inactivation of cortisol also occurs in placenta. 11β-HSD1 is a predominant 11β-reductase *in vivo* that acts in many tissues to increase local intracellular glucocorticoid concentrations and thereby maintain adequate exposure of relatively low affinity glucocorticoid receptors to their ligand.

cortisone to cortisol with the isoform called 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1). The skin expresses this enzyme, explaining why cortisone cream can be effective. More importantly, the liver expresses 11β-HSD1 and can activate cortisone to cortisol, thereby completing the cortisol-cortisone shunt such that the kidney inactivates cortisol to cortisone and the liver can reactivate cortisone to cortisol. The expression of 11β-HSD1 in adipose tissue may contribute to abdominal obesity seen in metabolic syndrome without biochemical hypercortisolism.

Conversion and Excretion of Adrenal Androgens

Adrenal androgen metabolism results either in degradation and inactivation or the peripheral conversion of these weak androgens to their more potent derivatives testosterone and dihydrotestosterone. DHEA is readily converted within the adrenal to DHEA sulfate, the adrenal androgen secreted in greatest amount. DHEA secreted by the gland is also converted to DHEA sulfate by the liver and kidney, or it may be converted to Δ^4-androstenedione. DHEA sulfate may be excreted without further metabolism; however, both it and DHEA are also metabolized to 7α- and 16α-hydroxylated derivatives and by 17β reduction to Δ^5-androstenediol and its sulfate. Androstenedione is converted either to testosterone or by reduction of its 4,5 double bond to etiocholanolone or androsterone, which may be further converted by 17α reduction to etiocholanediol and androstanediol, respectively. Testosterone is converted to dihydrotestosterone in androgen-sensitive tissues by 5β reduction, and it, in turn, is mainly metabolized by 3α reduction to androstanediol. The metabolites of these androgens are conjugated either as glucuronides or sulfates and excreted in the urine.

BIOLOGIC EFFECTS OF ADRENAL STEROIDS

Glucocorticoids

Although glucocorticoids were originally so called because of their influence on glucose metabolism, they are currently defined as steroids that exert their effects by binding to specific cytosolic receptors that mediate the actions of these hormones. These glucocorticoid receptors are present in virtually all tissues, and glucocorticoid-receptor interaction is responsible for most of the known effects of these steroids. Alterations in the structure of the glucocorticoids have led to the development of synthetic compounds with greater glucocorticoid activity. The increased activity of these compounds is due to increased affinity for the glucocorticoid receptors and delayed plasma clearance, which increases tissue exposure. In addition, many of these synthetic glucocorticoids have negligible mineralocorticoid effects and thus do not result in sodium retention, hypertension, and hypokalemia. This section describes the molecular mechanisms of glucocorticoid action and the effects on individual metabolic functions and tissues (Table 9–2).

Molecular Mechanisms

Glucocorticoid action is initiated by entry of the steroid into the cell and binding to the cytosolic glucocorticoid–receptor proteins (see Figures 1–13, 1–15, and 1–16). The most abundant cytoplasmic glucocorticoid–receptor complex includes two subunits of the 90-kDa heat shock protein (hsp) 90. After binding, the hsp90 subunits dissociate and activated hormone–receptor complexes enter the nucleus and interact with nuclear chromatin acceptor sites. The DNA-binding domain of the receptor is a cysteine-rich region which, when it chelates zinc, assumes a conformation called a zinc finger. The receptor–glucocorticoid complex acts via two mechanisms: (1) binding to specific sites in nuclear DNA, the glucocorticoid regulatory elements; and (2) interactions with other transcription factors such as nuclear factor κB, an important regulator of cytokine genes. These result in altered expression of specific genes and the transcription of specific mRNAs. The resulting proteins elicit the glucocorticoid response, which may be inhibitory or stimulatory depending on the specific gene and tissue affected. Although glucocorticoid receptors are similar in many tissues, the proteins synthesized in response to glucocorticoids vary widely and are the result of expression of specific genes in different cell types. The mechanisms underlying this specific regulation are unknown. Analyses of cloned complementary DNAs for human glucocorticoid receptors have revealed marked structural and amino acid sequence homology between glucocorticoid receptors and receptors for other steroid hormones (eg, mineralocorticoids, estrogen, progesterone) as well as for thyroid hormone and the oncogene v-*erb*-A. Although the steroid-binding domain of the glucocorticoid receptor confers specificity for glucocorticoid binding, glucocorticoids such as cortisol and corticosterone bind to the mineralocorticoid receptor with an affinity equal to that of aldosterone. Mineralocorticoid receptor specificity is maintained by the expression of 11β-HSD in classic mineralocorticoid-sensitive tissues—the cortisol-cortisone shunt (see earlier).

Although glucocorticoid–receptor complexes and their subsequent regulation of gene expression are responsible for most glucocorticoid effects, other effects may occur through plasma membrane receptors.

Glucocorticoid Agonists and Antagonists

The study of glucocorticoid receptors has led to the definition of glucocorticoid agonists and antagonists. These studies have also identified a number of steroids with mixed effects termed partial agonists, partial antagonists, or partial agonist–partial antagonists. In addition, novel glucocorticoid receptor ligands are being developed that have more selectivity in terms of receptor binding or transcription of specific genes.

A. Agonists   In humans, cortisol, synthetic glucocorticoids (eg, prednisolone, dexamethasone), corticosterone, and aldosterone are glucocorticoid agonists. The synthetic glucocorticoids have substantially higher affinity for the glucocorticoid receptor, and these have greater glucocorticoid activity than cortisol when

TABLE 9–2 The main targets and actions of glucocorticoids and the consequences of Cushing disease and Addison disease.

Target System	Specific Target	Physiologic Function	Cushing Disease	Addison Disease
Intermediary metabolism	Liver	Increased expression of gluconeogenic enzymes, phosphoenolpyruvate car-boxykinase, glucose-6-phosphatase, and fructose-2,6-bisphosphatase	Increased hepatic glucose output; together with insulin, increased hepatic glycogen stores	Diminished hepatic glucose output and glycogen stores
	Adipose tissue	Permissive for lipolytic signals (catechol-amines, GH) leading to elevated plasma FFA to fuel gluconeogenesis	Overall effect (together with insulin): central obesity (truncal obesity, moon facies, and buffalo hump)	Decreased adiposity and decreased lipolysis
	Skeletal muscle	Degradation of fibrillar muscle proteins by activating the ubiquitin pathway, thereby providing amino acid sub-strates for gluconeogenesis	Muscle weakness and wasting mainly in proximal muscles; increased urinary nitrogen excre-tion (urea from amino acids)	Muscle weakness, decreased muscle glycogen stores; decreased urinary nitrogen excretion
	Plasma glucose	Maintains plasma glucose during fasting (anti-hypoglycemic action); increases plasma glucose during stress (hyper-glycemic action)	Impaired glucose tolerance, insulin-resistant diabetes mellitus; increased plasma glucose is due to decreased peripheral glucose utilization and increased hepatic glucose output	Hypoglycemia, increased insulin sensitivity
Calcium homeostasis	Kidney	Decreased reabsorption of calcium	Hypercalciuria without hypercalce-mia leading to secondary hyperparathyroidism	Retardation of bone growth mainly through decreased GH; hypercalcemia possible
	Bone, cartilage	Inhibition of collagen synthesis and bone deposition	Retardation of bone growth and bone age by direct action and by decreas-ing GH; osteoporosis in adults	
	Gastrointestinal tract	Inhibition of calcium, magnesium, and phosphate absorption by antagonizing calcitriol actions		
Other endocrine systems	Hypothalamus, pituitary	Decreases endogenous opioid produc-tion; depresses gonadotroph respon-siveness to GnRH; stimulates GH gene expression by the pituitary; inhibits GH secretion via the hypothalamus	Scanty menses due to suppressed gonadotroph sensitivity to GnRH; suppressed GH secretion by hypo-thalamic action; minimal suppres-sion of the TRH-TSH axis	Scanty menses by upregulated CRH-endogenous opioid pathway-mediated suppression of GnRH; suppressed GH secre-tion; hypothyroidism (if present) is due to autoimmune mechanism
	Pancreas	Inhibits insulin secretion by decreasing the efficacy of cytoplasmic Ca^{2+} on the exocytotic process	Absolute hyperinsulinemia with relative hypoinsulinemia (lower plasma insulin than expected for the degree of hyperglycemia)	Absolute hypoinsu-linemia with relative hyperinsulinemia
	Adrenal medulla	Increases PNMT expression and activity (epinephrine synthesis)	Increased responses to sympathoad-renal activation	Decreased responses to sympathoadrenal activation
	Carrier proteins (CBG, SHBG, TBG)	Decreases all major hormone-binding proteins	Decrease in total T_4, free T_4 remains normal	
Immune system	Thymus, lymphocytes	Causes age-related involution of the thymus; induces thymic atrophy	Immunocompromised state; lymphocytopenia	Relative lymphocytosis in peripheral blood
	Monocytes	Inhibits monocyte proliferation and antigen presentation; decreased production of IL-1, IL-6, and TNFα	Monocytopenia in peripheral blood	Monocytosis in periph-eral blood
	Granulocytes	Demargination of neutrophils by suppressing the expression of adhesion molecules	Peripheral blood: granulocytosis, eosinopenia	Peripheral blood: granulocytopenia, eosinophilia

(Continued)

TABLE 9–2 The main targets and actions of glucocorticoids and the consequences of Cushing disease and Addison disease. (*Continued*)

Target System	Specific Target	Physiologic Function	Cushing Disease	Addison Disease
	Inflammatory response	Inhibition of inflammation by inhibiting PLA_2, thereby inhibiting production of leukotrienes and prostaglandins; suppresses COX-2 expression		
	Erythrocytes	No significant effect	Increased hemoglobin and hematocrit are due to ACTH-mediated overproduction of androgens	Anemia is more pronounced in women and is due to loss of adrenal androgens; anemia may be related to direct autoimmune targeting of gastric parietal cells
Skin and connective tissue		Antiproliferative for fibroblasts and keratinocytes	Easy bruisability due to dermal atrophy; striae or sites of increased tension, especially sites of adipose tissue accumulation; poor wound healing; hirsutism and acne are due to ACTH-mediated increase of adrenal androgens; hyperpigmentation is a direct effect of ACTH on melanocortin 1 receptors	Darkening of the skin is due to ACTH-mediated stimulation of epidermal melanocortin 1 receptors; vitiligo may occur due to direct autoimmune destruction of melanocytes in circumscribed areas
Breast	Mammary epithelium	Mandatory requirement for lactation	Cushing disease may be associated with galactorrhea	Addison disease is not associated with galactorrhea
Lung	Type 2 alveolar cell	Stimulation of surfactant production		
Cardiovascular system	Heart	Increased contractility	Hypertension	Lower peripheral resistance; hypotension with further postural decrease in blood pressure (orthostatic hypotension); low-voltage ECG
	Vasculature	Increased vascular reactivity to vasoconstrictors (catecholamines, angiotensin II)		
Na^+, K^+, and ECF volume	Kidney	Increased GFR and nonphysiologic actions on mineralocorticoid receptors	Hypokalemic alkalosis, increased ECF volume due to mineralocorticoid activity (increased DOC, saturation of type 2 11β-hydroxysteroid dehydrogenase by high levels of cortisol)	Hyponatremia, hyperkalemic acidosis, and decreased ECF volume are mainly due to loss of mineralocorticoid activity
	Posterior pituitary		Hyponatremia due to SIADH	Increased ADH mainly via hypovolemia-related baroreceptor mechanism
Psychiatric parameters of CNS function	Mood	Eucortisolemia maintains emotional balance	Initially, euphoria; long-term, depression, psychosis	Depression
	Appetite	Increases appetite	Hyperphagia	Decreased appetite in spite of improved taste and smell
	Sleep	Suppression of REM sleep	Sleep disturbances	
	Memory	Sensitizes hippocampal glutamate receptors, induces atrophy of dendrites	Impaired memory, bilateral hippocampal atrophy	
	Eye	Increasing intraocular pressure	Cataract formation; increased intraocular pressure	Decreased intraocular pressure

present in equimolar concentrations. Corticosterone and aldosterone have substantial affinity for the glucocorticoid receptor; however, their plasma concentrations are normally much lower than that of cortisol, and thus these steroids do not have significant physiologic glucocorticoid effects.

B. Antagonists   Glucocorticoid antagonists bind to the glucocorticoid receptors but do not elicit the nuclear events required to cause a glucocorticoid response. These steroids compete with agonist steroids such as cortisol for the receptors and thus inhibit agonist responses. Other steroids have partial agonist activity when present alone (ie, they elicit a partial glucocorticoid response). However, in sufficient concentration, they compete with agonist steroids for the receptors and thus competitively inhibit agonist responses; that is, these partial agonists may function as partial antagonists in the presence of more active glucocorticoids. Steroids such as progesterone, 11-deoxycortisol, DOC, testosterone, and 17β-estradiol have antagonist or partial agonist-partial antagonist effects; however, the physiologic role of these hormones in glucocorticoid action is probably negligible, because they circulate in low concentrations. The antiprogestational agent mifepristone has substantial glucocorticoid antagonist properties and has been used to block glucocorticoid action in patients with Cushing syndrome.

Intermediary Metabolism (Table 9–2)

Glucocorticoids in general inhibit DNA synthesis. In addition, in most tissues they inhibit RNA and protein synthesis and accelerate protein catabolism. These actions provide substrate for intermediary metabolism; however, accelerated catabolism also accounts for the deleterious effects of glucocorticoids on muscle, bone, connective tissue, and lymphatic tissues. In contrast, RNA and protein synthesis in liver is stimulated.

A. Hepatic glucose metabolism   Glucocorticoids increase hepatic gluconeogenesis by stimulating the gluconeogenic enzymes phosphoenolpyruvate carboxykinase and glucose-6-phosphatase. They have a permissive effect in that they increase hepatic responsiveness to the gluconeogenic hormone glucagon, and they also increase the release of substrates for gluconeogenesis from peripheral tissues, particularly muscle. This latter effect may be enhanced by the glucocorticoid-induced reduction in peripheral amino acid uptake and protein synthesis. Glucocorticoids also increase glycerol and free fatty acid release by lipolysis and increase muscle lactate release. They enhance hepatic glycogen synthesis and storage by stimulating glycogen synthetase activity and to a lesser extent by inhibiting glycogen breakdown. These effects are insulin dependent.

B. Peripheral glucose metabolism   Glucocorticoids also alter carbohydrate metabolism by inhibiting peripheral glucose uptake in muscle and adipose tissue. This effect and the others described earlier may result in increased insulin secretion in states of chronic glucocorticoid excess.

C. Effects on adipose tissue   In adipose tissue, the predominant effect is increased lipolysis with release of glycerol and free fatty acids. This is partially due to direct stimulation of lipolysis by glucocorticoids, but it is also contributed to by decreased glucose uptake and enhancement by glucocorticoids of the effects of lipolytic hormones. Although glucocorticoids are lipolytic, increased fat deposition is a classic manifestation of glucocorticoid excess. This paradox may be explained by the increased appetite caused by high levels of these steroids and by the lipogenic effects of the hyperinsulinemia that occurs in this state. The reason for abnormal fat deposition and distribution in states of cortisol excess is unknown. In these instances, fat is classically deposited centrally in the face, cervical area, trunk, and abdomen; the extremities are usually spared.

D. Summary   The effects of the glucocorticoids on intermediary metabolism can be summarized as follows:

1. Effects are minimal in the fed state. However, during fasting, glucocorticoids contribute to the maintenance of plasma glucose levels by increasing gluconeogenesis and decreasing uptake of glucose by adipose tissue.
2. Hepatic glucose production is enhanced, as is hepatic RNA and protein synthesis.
3. The effects on muscle are catabolic (ie, decreased glucose uptake and metabolism, decreased protein synthesis, and increased release of amino acids). This provides amino acid substrates for gluconeogenesis in the liver.
4. In adipose tissue, lipolysis is stimulated. This increases fatty acid delivery to the liver where their metabolism provides energy to support gluconeogenesis.
5. In glucocorticoid deficiency, hypoglycemia may result, whereas in states of glucocorticoid excess there may be hyperglycemia, hyperinsulinemia, muscle wasting, and weight gain with abnormal fat distribution.

Effects on Other Tissues and Functions (Table 9–2)

A. Connective tissue   Glucocorticoids in excess inhibit fibroblasts, lead to loss of collagen and connective tissue, and thus result in thinning of the skin, easy bruising, stria formation, and poor wound healing.

B. Bone   The physiologic role of glucocorticoids in bone metabolism and calcium homeostasis is unknown; however, in excess, they have major deleterious effects. Glucocorticoids directly inhibit bone formation by decreasing osteoblast proliferation and the synthesis of RNA, protein, collagen, and hyaluronate. Initially, supraphysiologic doses of glucocorticoids also stimulate bone resorption, at least in part via activation of the receptor activator of nuclear factor kappa B (RANK)-ligand/ RANK signaling that is osteoclastogenic. This leads to osteolysis and increased biochemical markers of bone turnover. In addition, glucocorticoids may potentiate the proresorptive actions of parathyroid hormone (PTH) and 1,25-dihydroxycholecalciferol

$[1,25(OH)_2D_3]$ on bone, and this may further contribute to net bone resorption. Chronically, however, the key effect to promote bone loss is the detrimental impact on bone formation (see Chapter 8).

C. Calcium metabolism   Glucocorticoids also have other major effects on mineral homeostasis. They markedly reduce intestinal calcium absorption, which tends to lower serum calcium. This theoretically promotes a state of secondary hyperparathyroidism to maintain the serum calcium within the normal range. In reality, however, chronic elevations in intact PTH levels have been difficult to demonstrate consistently in patients on glucocorticoid therapy. The mechanism of decreased intestinal calcium absorption is thought to result from antagonism of $1,25(OH)_2D$ action in the intestine. It is not due to decreased synthesis or decreased serum levels of the active vitamin D metabolites; in fact, $1,25(OH)_2D$ levels are normal or even increased in the presence of glucocorticoid excess. Increased $1,25(OH)_2D$ synthesis in this setting may result from decreased serum phosphorus levels (see later), increased PTH secretion, direct stimulation by glucocorticoids of renal 1α-hydroxylase, and or reduced target cell (intestine) responsiveness. Glucocorticoids increase urinary calcium excretion, and hypercalciuria is a frequent feature of cortisol excess. They also reduce the tubular reabsorption of phosphate, leading to phosphaturia and decreased serum phosphorus concentrations.

Thus, glucocorticoids in excess result in negative calcium balance, with decreased calcium absorption and increased urinary calcium excretion. Serum calcium levels are maintained, but at the expense of net bone resorption. Decreased bone formation and increased resorption ultimately result in the disabling osteoporosis that is often a major complication of spontaneous and iatrogenic glucocorticoid excess (see Chapter 8).

D. Growth and development   Glucocorticoids accelerate the development of a number of systems and organs in fetal and differentiating tissues, although the mechanisms are unclear. As discussed earlier, glucocorticoids are generally inhibitory, and these stimulatory effects may be due to glucocorticoid interactions with other growth factors. Examples of these development-promoting effects are increased surfactant production in the fetal lung and the accelerated development of hepatic and gastrointestinal enzyme systems.

Glucocorticoids in excess inhibit growth in children, and this adverse effect is a major complication of therapy. This may be a direct effect on bone cells, although decreased growth hormone (GH) secretion and insulin-like growth factor I generation also contribute (see Chapter 6).

E. Blood cells and immunologic function

1. **Erythrocytes**—Glucocorticoids have little effect on erythropoiesis and hemoglobin concentration. Although mild polycythemia and anemia may be seen in Cushing syndrome and Addison disease, respectively, these alterations are more likely to be secondary to altered androgen metabolism.

2. **Leukocytes**—Glucocorticoids influence both leukocyte movement and function. Thus, glucocorticoid administration increases the number of intravascular polymorphonuclear neutrophils/leukocytes (PMNs) by increasing PMN release from bone marrow, by increasing the circulating half-life of PMNs, and by decreasing PMN movement out of the vascular compartment. Glucocorticoid administration reduces the number of circulating lymphocytes, monocytes, and eosinophils, mainly by increasing their movement out of the circulation and may be lympholytic as well. The converse (ie, neutropenia, lymphocytosis, monocytosis, and eosinophilia) is seen in adrenal insufficiency. Glucocorticoids also decrease the migration of inflammatory cells (PMNs, monocytes, and lymphocytes) to sites of injury, and this is probably a major mechanism of the anti-inflammatory actions and increased susceptibility to infection that occur following chronic administration. Glucocorticoids also decrease lymphocyte production and the mediator and effector functions of these cells.

3. **Immunologic effects**—Glucocorticoids influence multiple aspects of immunologic and inflammatory responsiveness, including the mobilization and function of leukocytes, as discussed earlier. They inhibit phospholipase A_2, a key enzyme in the synthesis of prostaglandins. This inhibition is mediated by a class of peptides called lipocortins or annexins. They also impair the release of effector substances such as the lymphokine IL-1, antigen processing, antibody production and clearance, and other specific bone marrow-derived and thymus-derived lymphocyte functions. The immune system, in turn, affects the HPA axis; IL-1 stimulates the secretion of CRH and ACTH. Although traditionally used as anti-inflammatory and/or immunosuppressive agents, glucocorticoids, especially at lower doses, also have stimulatory and permissive effects on the inflammatory response to injury.

F. Cardiovascular function   Glucocorticoids may increase cardiac output, and they also increase peripheral vascular tone, possibly by augmenting the effects of other vasoconstrictors (eg, the catecholamines). Glucocorticoids also regulate expression of adrenergic receptors. Thus, refractory shock may occur when the glucocorticoid-deficient individual is subjected to stress. Glucocorticoids in excess may cause hypertension independently of their mineralocorticoid effects. Although the incidence and the precise cause of this problem are unclear, it is likely that the mechanism involves the renin-angiotensin system; glucocorticoids regulate renin substrate, angiotensinogen, the precursor of angiotensin I.

G. Renal function   These steroids affect water and electrolyte balance by actions mediated either by mineralocorticoid receptors (sodium retention, hypokalemia, and hypertension) or via glucocorticoid receptors (increased glomerular filtration rate due to increased cardiac output or due to direct renal effects on salt and water retention). Thus, corticosteroids such as betamethasone or dexamethasone, which have little mineralocorticoid activity, increase sodium and water excretion. Glucocorticoid-deficient subjects have decreased glomerular filtration rates and are unable to excrete a water load. This may be further aggravated by increased ADH secretion, which may occur in glucocorticoid deficiency.

H. Central nervous system function Glucocorticoids readily enter the brain, and although their physiologic role in central nervous system function is unknown, their excess or deficiency may profoundly alter behavior and cognitive function.

1. **Excessive glucocorticoids**—In excess, the glucocorticoids initially cause euphoria; however, with prolonged exposure, a variety of psychologic abnormalities occur, including irritability, emotional lability, and depression. Hyperkinetic or manic behavior is less common; overt psychoses occur in a small number of patients, particularly those with underlying bipolar disorder. Many patients also note impairment in cognitive functions, most commonly memory and concentration. Other central effects include increased appetite, decreased libido, and insomnia, with decreased rapid eye movement sleep and increased stage II sleep.
2. **Decreased glucocorticoids**—Patients with Addison disease are apathetic and depressed and tend to be irritable, negativistic, and reclusive. They have decreased appetite but increased sensitivity of taste and smell mechanisms.

I. Effects on other hormones

1. **Thyroid function**—Glucocorticoids in excess affect thyroid function. Thyroid-stimulating hormone (TSH) synthesis and release are inhibited by glucocorticoids, and TSH responsiveness to thyrotropin-releasing hormone (TRH) is frequently subnormal. Although basal levels are usually normal, the TSH concentration may be acutely low in patients treated with moderate- to high-dose glucocorticoids. Serum total thyroxine (T_4) concentrations are usually low normal because of a decrease in thyroxine-binding globulin, but free T_4 levels are normal. Total and free T_3 (triiodothyronine) concentrations may be low, because glucocorticoid excess decreases the conversion of T_4 to T_3 and increases conversion to reverse T_3. Despite these alterations, manifestations of hypothyroidism are not apparent.
2. **Gonadal function**—Glucocorticoids also affect gonadotropin and gonadal function. In males, they inhibit gonadotropin secretion, as evidenced by decreased responsiveness to administered gonadotropin-releasing hormone (GnRH) and subnormal plasma testosterone concentrations. In females, glucocorticoids also suppress luteinizing hormone (LH) responsiveness to GnRH, resulting in suppression of estrogens and progestins with inhibition of ovulation and amenorrhea.

J. Miscellaneous effects

1. **Peptic ulcer**—The role of steroid excess in the production or reactivation of peptic ulcer disease is controversial. However, there appears to be a modest independent effect of glucocorticoids to promote peptic ulcer disease (relative risk about 1.4), and when this effect is combined with that of nonsteroidal anti-inflammatory drugs, there is a synergistic interaction that considerably increases the risk.
2. **Ophthalmologic effects**—Intraocular pressure varies with the level of circulating glucocorticoids and parallels the circadian variation of plasma cortisol levels. In addition, glucocorticoids in excess increase intraocular pressure in patients with open-angle glaucoma. Glucocorticoid therapy may also cause cataract formation. Central serous chorioretinopathy, an accumulation of subretinal detachment, may also complicate endogenous or exogenous glucocorticoid excess.

ADRENAL ANDROGENS

The direct biologic activity of the adrenal androgens (androstenedione, DHEA, and DHEA sulfate) is minimal, and they function primarily as precursors for peripheral conversion to the active androgenic hormones, testosterone and dihydrotestosterone. Thus, DHEA sulfate secreted from the adrenal undergoes limited conversion to DHEA; this peripherally converted DHEA and that secreted by the adrenal cortex can be further converted in peripheral tissues to androstenedione, the immediate precursor of the active androgens.

The actions of testosterone and dihydrotestosterone are described in Chapter 12. This section deals only with the adrenal contribution to androgenicity.

Effects in Males

In males with normal gonadal function, the conversion of adrenal androstenedione to testosterone accounts for less than 5% of the production rate of this hormone, and thus the physiologic effect is negligible. In adult males, excessive adrenal androgen secretion has no clinical consequences; however, in boys, it causes premature penile enlargement and early development of secondary sexual characteristics.

Effects in Females

In females, the adrenal substantially contributes to total androgen production by the peripheral conversion of androstenedione to testosterone. In the follicular phase of the menstrual cycle, adrenal precursors account for two-thirds of testosterone production and one-half of dihydrotestosterone production. During midcycle, the ovarian contribution increases, and the adrenal precursors account for only 40% of testosterone production.

In females, abnormal adrenal function as seen in Cushing syndrome, adrenal carcinoma, and congenital adrenal hyperplasia results in excessive secretion of adrenal androgens, and their peripheral conversion to testosterone results in androgen excess, manifested by acne, hirsutism, and virilization.

LABORATORY EVALUATION

Cortisol and the adrenal androgens are measured by specific plasma assays. Certain urinary assays, particularly measurement of 24-hour urine free cortisol, are also useful. In addition, plasma concentrations of ACTH can be determined. The assays for plasma steroids commonly used measure the total hormone concentrations and are therefore influenced by alterations in plasma-binding proteins. Furthermore, because ACTH and the plasma concentrations of the adrenal hormones fluctuate markedly (see Figure 9–6), single plasma measurements are frequently unreliable. Thus, plasma levels must be interpreted cautiously, and more

specific diagnostic information is usually obtained by performing appropriate dynamic tests (stimulation and suppression) or other tests that reflect cortisol secretory rate.

Plasma ACTH

A. Methods of measurement   Plasma ACTH measurements are extremely useful in the diagnosis of pituitary-adrenal dysfunction. The typical reference range for plasma ACTH, using a sensitive immunoradiometric assay (IRMA) or immunochemiluminometric assay (ICMA), is 9 to 52 pg/mL (2-11.1 pmol/L).

B. Interpretation   Plasma ACTH levels are most useful in differentiating pituitary causes from adrenal causes of adrenal dysfunction as follows:

1. In adrenal insufficiency due to primary adrenal disease, plasma ACTH levels are elevated. Conversely, in pituitary ACTH deficiency and secondary hypoadrenalism, plasma ACTH levels are frankly low or inappropriately within the normal reference range.
2. In Cushing syndrome due to primary glucocorticoid-secreting adrenal tumors, plasma ACTH is suppressed, and typically less than the lower limit of the normal reference range. In patients with Cushing disease (pituitary ACTH hypersecretion), plasma ACTH levels are inappropriately normal or elevated.
3. Plasma ACTH levels are usually markedly elevated in the ectopic ACTH syndrome, but there is a considerable amount of overlap with levels seen in Cushing disease. In addition, values lower than expected may be observed rarely in ectopic ACTH syndrome when the two-site IRMA is used; this assay may not detect high-molecular-weight precursors of ACTH that can be produced in ectopic ACTH syndrome.
4. Plasma ACTH levels are also elevated in patients with the common forms of congenital adrenal hyperplasia and are useful in the diagnosis and management of these disorders (see Chapter 14).

Plasma Cortisol

A. Methods of measurement   The most common methods of measurement of plasma cortisol are radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), high-performance liquid chromatography (HPLC), and liquid chromatography tandem mass spectroscopy (LC/MS/MS). These methods measure total cortisol (both bound and free) in plasma. Most commonly used drugs and medications do not interfere with this assay. In contrast to radioimmunoassays, HPLC and LC/MS/MS do not demonstrate cross-reactivity with synthetic glucocorticoids.

B. Interpretation   The diagnostic utility of single plasma cortisol concentrations is limited by the episodic nature of cortisol secretion and its appropriate elevations during stress. As explained later, more information is obtained by dynamic testing of the HPA axis. Reference ranges for cortisol depend on the methodology used. With the introduction of more specific cortisol assays (eg, LC/MS/MS), the normal range for cortisol in the basal state and after dynamic testing may be lower than currently accepted ranges.

1. **Normal values**—Normal plasma cortisol levels vary with the method used and time of day the sample is obtained. With radioimmunoassay, levels at 8 AM range from 3 to 20 μg/dL (80-550 nmol/L) and average 10 to 12 μg/dL (275.9-331.1 nmol/L). Values obtained later in the day are lower and at 4 PM are approximately half of morning values. At 10 PM to 2 AM, the plasma cortisol concentrations by these methods are usually less than 3 μg/dL (80 nmol/L).
2. **Levels during stress**—Cortisol secretion increases in patients who are acutely ill, during surgery, and following trauma when plasma concentrations may reach greater than 40 to 60 μg/dL (1100-1655 nmol/L).
3. **High-estrogen states**—The total plasma cortisol concentration is also elevated with increased CBG-binding capacity, which occurs most commonly when circulating estrogen levels are high (eg, during pregnancy and when exogenous estrogens or oral contraceptives are being used). In these situations, plasma cortisol may reach levels two to three times normal.
4. **Other conditions**—CBG levels may be increased or decreased in other situations, as discussed earlier in the sections on circulation and metabolism. Total plasma cortisol concentrations may also be increased in severe anxiety, endogenous depression, starvation, anorexia nervosa, alcoholism, and chronic kidney disease.

Salivary Cortisol

Cortisol in the saliva is in equilibrium with the free and biologically active cortisol in the blood. Salivary cortisol concentrations are not affected by changes in serum cortisol–binding proteins, by salivary flow or composition, and they are stable at room temperature for many days. Measurements of salivary cortisol can be obtained from late-night, ambulatory saliva samples, which are used as a means of establishing the presence or absence of Cushing syndrome. Salivary cortisol may also be used to obtain accurate free cortisol levels in patients with abnormal serum-binding proteins.

A. Methods of measurement   Saliva can easily be sampled at home by the patient using a variety of techniques, including the use of a commercially available sampling device or by passive drooling. The same methods that are employed to measure plasma cortisol, radioimmunoassay, ELISA, HPLC, and LC/MS/MS, are used to measure salivary cortisol concentrations.

B. Interpretation

1. **Normal values**—Reference ranges for late-night salivary cortisol concentrations are dependent on the assays employed, but with radioimmunoassay and ELISA, the normal salivary cortisol level at midnight is generally less than 0.15 μg/dL (4 nmol/L).
2. **Diagnostic utility**—As with single plasma cortisol measurements, randomly obtained salivary cortisol concentrations are of limited use. However, plasma and salivary cortisol in normal individuals reach a nadir from 10 PM to 2 AM. Patients with Cushing syndrome do not reach a normal nadir at this time, and several studies have shown that elevated late-night salivary cortisol is a sensitive and specific diagnostic test for Cushing syndrome.

Plasma Free Cortisol

This assay measures the free or biologically active fraction of plasma cortisol and, thus, is not influenced by alterations in CBG and serum albumin. The best current method involves equilibrium dialysis to separate bound and free hormone followed by measurement of the free fraction by radioimmunoassay. In patients with normal serum albumin and CBG, the free cortisol correlates well with total cortisol levels; however, in patients with disturbances in plasma-binding proteins, this correlation is lost.

Although this assay is not in common use, it is of importance in the assessment of adrenal function in patients with critical illness. In these patients the measurement of total plasma cortisol and its response to ACTH has overestimated the number of patients with adrenal insufficiency, especially in the most severely ill patients who frequently have hypoalbuminemia and subnormal CBG levels.

Urinary Corticosteroids

A. Free cortisol

1. **Methods of measurement**—The assay of unbound cortisol excreted in the urine is another method for the diagnosis of Cushing syndrome. Normally, less than 1% of the secreted cortisol is excreted unchanged in the urine. However, in states of excess secretion, the binding capacity of CBG is exceeded, and plasma free cortisol increases, as does its urinary excretion. Urine free cortisol is measured in a 24-hour urine collection by HPLC, radioimmunoassay, and now, most commonly, by LC/MS/MS.
2. **Normal values**—HPLC and LC/MS/MS provide the most specific measurement of cortisol and are the current procedures of choice. The reference range for urine free cortisol assayed by HPLC or LC/MS/MS is generally 5 to 50 μg/24 h (14-135 nmol/24 h).
3. **Diagnostic utility**—This method has historically been the gold standard for diagnosis of Cushing syndrome, but recent studies questions the sensitivity of this test. Interestingly, the levels of urine free cortisol may be elevated in the same conditions that increase total plasma cortisol (see earlier), including a slight elevation during pregnancy and women taking oral contraceptives. This test is not useful in adrenal insufficiency, because it lacks sensitivity at low levels and because low cortisol excretion is often found in normal persons.

B. 17-Hydroxycorticosteroids
These urinary steroids are largely of historical interest and should not be measured at present because of the greater utility of plasma cortisol and urine free cortisol measurements.

Dexamethasone Suppression Tests

A. Low-Dose test
This procedure is used to establish the presence of Cushing syndrome regardless of its cause. Dexamethasone, a potent glucocorticoid, normally suppresses pituitary ACTH release with a resulting fall in plasma and urine cortisol, thus assessing feedback inhibition of the HPA axis. In Cushing syndrome, this mechanism is abnormal, and steroid secretion fails to be suppressed in the normal way.

Dexamethasone, in the doses used, does not interfere with the measurement of plasma and urinary cortisol.

The overnight 1-mg dexamethasone suppression test is commonly used as a screening test for Cushing syndrome. Dexamethasone, 1 mg orally, is given as a single dose at 11:00 PM, and the following morning a plasma sample is obtained for cortisol determination. Cushing syndrome is probably excluded if the serum or plasma cortisol level is less than 1.8 μg/dL (50 nmol/L). Utilizing this criterion leads to very high sensitivity but also has an increased false-positive rate and results in a specificity of 80% to 90%.

False-positive results occur in hospitalized and chronically ill patients. Acute illness, depression, anxiety, alcoholism, high-estrogen states, and uremia may also cause false-positive results. Patients taking phenytoin, barbiturates, and other inducers of hepatic microsomal enzymes may have accelerated metabolism of dexamethasone and thus fail to achieve adequate plasma levels to suppress ACTH.

B. High-dose tests
High-dose dexamethasone suppression testing has historically been used to differentiate Cushing disease (pituitary ACTH hypersecretion) from ectopic ACTH and adrenal tumors. This rationale has been based on the fact that in some patients with Cushing disease, the HPA axis is suppressible with supraphysiologic doses of glucocorticoids, whereas cortisol secretion is autonomous in patients with adrenal tumors and in most patients with the ectopic ACTH syndrome. Unfortunately, exceptions to these rules are so common that high-dose dexamethasone suppression testing must be interpreted with extreme caution.

1. **Overnight high-dose dexamethasone suppression test**—After a baseline morning cortisol specimen is obtained, a single dose of dexamethasone, 8 mg orally, is administered at 11:00 PM and plasma cortisol is measured at 8:00 AM the following morning. Generally, patients with Cushing disease suppress plasma cortisol level to less than 50% of baseline values—in contrast to patients with the ectopic ACTH syndrome, who fail to suppress to this level. Patients with cortisol-producing adrenal tumors also fail to suppress: their cortisol secretion is autonomous, and ACTH secretion is already suppressed by the high endogenous levels of cortisol.
2. **Two-day high-dose dexamethasone suppression test**—This test has been used to differentiate patients with Cushing disease from those with an ectopic ACTH syndrome. It is performed by administering dexamethasone, 2 mg orally every 6 hours for 2 days. Twenty-four-hour urine samples are collected before and on the second day of dexamethasone administration. Patients with Cushing disease have a reduction of urine cortisol excretion to less than 50% of baseline values, whereas those with adrenal tumors or the ectopic ACTH syndrome usually have little or no reduction in urinary cortisol excretion. However, some patients with an ectopic ACTH-secreting neoplasm suppress steroid secretion with high doses of dexamethasone, and some patients with pituitary ACTH-dependent Cushing syndrome fail to suppress to these levels. The diagnostic sensitivity, specificity, and accuracy of the high-dose dexamethasone suppression test are only about 80%. Better specificity and accuracy can be achieved by utilizing different criteria. However, it has become increasingly clear that high-dose

dexamethasone suppression testing, regardless of the criteria employed, cannot distinguish pituitary from nonpituitary ACTH hypersecretion with certainty. Currently, the only biochemical test with a high enough diagnostic accuracy to distinguish between these causes is inferior petrosal sinus ACTH sampling.

Pituitary-Adrenal Reserve

These tests are used to evaluate the ability of the HPA axis to respond to stress. ACTH administration directly stimulates adrenal secretion; metyrapone inhibits cortisol synthesis, thereby stimulating pituitary ACTH secretion; and insulin-induced hypoglycemia stimulates ACTH release by increasing CRH secretion. More recently, CRH has been utilized to directly stimulate pituitary corticotrophs to release ACTH. The relative utility of these procedures is discussed later in the section on adrenocortical insufficiency and also in Chapter 4.

A. ACTH stimulation testing

1. **Procedure and normal values—High-dose ACTH stimulation test**. The rapid ACTH stimulation test measures the acute adrenal response to ACTH and is used to diagnose both primary and secondary adrenal insufficiency. A synthetic human α^{1-24}-ACTH called tetracosactin or cosyntropin is used. Fasting is not required, and the test may be performed at any time of the day. A baseline cortisol sample is obtained; cosyntropin is administered in a dose of 250 µg intramuscularly or intravenously; and additional samples for plasma cortisol are obtained at 30 and/or 60 minutes following the injection. Because the peak concentration of ACTH with this test achieves a pharmacologic level exceeding 10,000 pg/mL, this study assesses maximal adrenocortical capacity. The peak cortisol response, 30 to 60 minutes later, should exceed 18 to 20 µg/dL (>497-552 nmol/L). The 30-minute peak cortisol response to ACTH is constant and is unrelated to the basal cortisol level. In fact, there is no difference in the peak cortisol level at 30 minutes regardless of whether 250 µg, 5 µg, or even 1 µg of ACTH is administered. Early studies of the salivary or plasma free cortisol response to ACTH suggest that this method may be useful in patients with abnormal levels of cortisol-binding proteins.

    Low-dose ACTH stimulation test. Since the standard or high-dose test may be normal in patients with partial secondary adrenal insufficiency, a low-dose (1 µg) ACTH stimulation test was developed. Although some studies reported increased sensitivity and specificity, two meta-analyses did not establish a distinct advantage for the low-dose test.

    To perform the low-dose test appropriately it must be undertaken in the morning and the ACTH must be given intravenously. In addition, technical limitations are significant (ie, ACTH is available only in 250-µg vials, it is unstable in solution, and adheres to glass and plastic syringes and IV tubing). Thus, there are serious issues as to the accuracy of the dose of ACTH during reconstitution, dilution, and IV injection. For these reasons, the low-dose ACTH stimulation test is not practical for routine clinical practice.

2. **Subnormal responses**—If the cortisol response to the rapid ACTH stimulation test is inadequate, adrenal insufficiency is present. In primary adrenal insufficiency, destruction of cortical cells reduces cortisol secretion and increases pituitary ACTH secretion. Therefore, the adrenal is already maximally stimulated, and there is no further increase in cortisol secretion when exogenous ACTH is given; that is, there is decreased adrenal reserve. In secondary adrenal insufficiency due to ACTH deficiency, there is atrophy of the zonae fasciculata and reticularis, and the adrenal thus is either hyporesponsive or unresponsive to acute stimulation with exogenous ACTH. In either primary or secondary types, a subnormal response to the rapid ACTH stimulation test accurately predicts deficient responsiveness of the axis to insulin hypoglycemia, metyrapone, and surgical stress.

3. **Normal responses**—A normal response to the rapid ACTH stimulation test excludes both primary adrenal insufficiency (by directly assessing adrenal reserve) and overt secondary adrenal insufficiency with adrenal atrophy. However, a normal response does not rule out partial ACTH deficiency (decreased pituitary reserve) in patients whose basal ACTH secretion is sufficient to prevent adrenocortical atrophy and patients with recently developed secondary adrenal insufficiency who have not yet undergone adrenal atrophy. These patients may be unable to further increase ACTH secretion and thus may have subnormal pituitary ACTH responsiveness to stress or hypoglycemia. In such patients, further testing with metyrapone, hypoglycemia, or CRH may be indicated. For further discussion, see the section on Diagnosis of Adrenocortical Insufficiency.

B. Metyrapone testing

Metyrapone testing has been used to diagnose adrenal insufficiency and to assess pituitary-adrenal reserve. The test procedures are detailed in Chapter 4. Metyrapone blocks cortisol synthesis by inhibiting the 11β-hydroxylase enzyme that converts 11-deoxycortisol to cortisol. This stimulates ACTH secretion, which in turn increases the secretion and plasma levels of 11-deoxycortisol. The overnight metyrapone test is most commonly used and is best suited to patients with suspected pituitary ACTH deficiency; patients with suspected primary adrenal failure are usually evaluated with the rapid ACTH stimulation test as described earlier and discussed in the section on Diagnosis of Adrenocortical Insufficiency. The normal response to the overnight metyrapone test is a plasma 11-deoxycortisol level greater than 7 mcg/dL (200 nmol/L) and a plasma ACTH level greater than 100 pg/mL (22 pmol/L) and indicates both normal ACTH secretion and adrenal function. A subnormal response establishes adrenocortical insufficiency. A normal response to metyrapone accurately predicts normal stress responsiveness of the hypothalamic-pituitary axis and correlates well with responsiveness to insulin-induced hypoglycemia. Metyrapone is only available directly from the manufacturer.

C. Insulin-induced hypoglycemia testing

The details of this procedure are described in Chapter 4. Hypoglycemia induces a central nervous system stress response, increases CRH release, and in this way increases ACTH and cortisol secretion. It therefore measures the integrity of the axis and its ability to respond to stress. In the non-acutely ill individual, the normal plasma cortisol response is an increment greater than 8 µg/dL (220 nmol/L) and a peak level greater than 18 to 20 µg/dL

(497-552 nmol/L). The plasma ACTH response to hypoglycemia is usually greater than 100 pg/mL (22 pmol/L). A normal plasma cortisol response to hypoglycemia excludes adrenal insufficiency and decreased pituitary reserve. Thus, patients with normal responses do not require cortisol therapy during illness or surgery.

D. CRH testing The procedure for CRH testing is described in Chapter 4. ACTH responses are exaggerated in patients with primary adrenal failure and absent in patients with hypopituitarism. Delayed responses may occur in patients with hypothalamic disorders. CRH testing has also been used to differentiate among the causes of Cushing syndrome (see later).

Androgens

Androgen excess is usually evaluated by the measurement of basal levels of these hormones, because suppression and stimulation tests are not as useful as in disorders affecting glucocorticoids. Assays are available for total plasma levels of DHEA, DHEA sulfate, androstenedione, testosterone, and dihydrotestosterone. Plasma-free testosterone (ie, testosterone not bound to SHBG) can be measured and is a more direct measure of circulating biologically active testosterone than the total plasma level, but commercially available methods vary widely in their accuracy (see Chapter 12).

DISORDERS OF ADRENOCORTICAL INSUFFICIENCY

Deficient adrenal production of glucocorticoids or mineralocorticoids results in adrenocortical insufficiency, which is either the consequence of destruction or dysfunction of the cortex (primary adrenocortical insufficiency, or Addison disease) or secondary to deficient pituitary ACTH secretion (secondary adrenocortical insufficiency). Glucocorticoid therapy is the most common cause of secondary adrenocortical insufficiency.

PRIMARY ADRENOCORTICAL INSUFFICIENCY (ADDISON DISEASE)

Etiology and Pathology (Figure 9–8)

The etiology of primary adrenocortical insufficiency has changed over time. Prior to 1920, tuberculosis was the major cause of adrenocortical insufficiency. Since 1950, autoimmune adrenalitis with adrenal atrophy has accounted for about 80% of cases. It is associated with a high incidence of other immunologic and autoimmune endocrine disorders (see later). Causes of primary adrenal insufficiency are listed in Table 9–3. Primary adrenocortical insufficiency, or Addison disease, is uncommon, with a reported prevalence of 35 to 140 per million population. When part of the polyglandular system, it is more common in females, with a

female:male ratio of approximately 2:1. Addison disease is usually diagnosed in the third to fifth decades.

A. Autoimmune adrenocortical insufficiency Pathologically, the adrenals are small and atrophic, and the capsule is thickened. The adrenal medulla is preserved, although cortical cells are largely absent, show degenerative changes, and are surrounded by a fibrous stroma and the characteristic lymphocytic infiltrates.

Autoimmune Addison disease is frequently accompanied by other immune disorders. There are two different syndromes in which autoimmune adrenal insufficiency may occur. The best characterized one is known as autoimmune polyendocrine syndrome type 1 (APS-1). This is generally an autosomal recessive disorder that usually presents in childhood and is accompanied by hypoparathyroidism, adrenal failure, and mucocutaneous candidiasis. APS-1 results in most cases from a mutation of the autoimmune regulator gene (*AIRE*), which is located on chromosome 21q22.3. These patients have impaired deletion of auto-reactive T cells during T cell development in the thymus. APS-1 has no relationship to human leukocyte antigen (HLA) and is often associated with autoimmune hepatitis, dystrophy of dental enamel and nails, alopecia, vitiligo, and keratopathy and may be accompanied by hypofunction of the gonads, thyroid, pancreatic B cell, and gastric parietal cells. Autoantibodies against the cholesterol side chain cleavage enzyme (P450scc, CYP11A1) and others have been described in patients with this disorder.

The more common presentation of autoimmune adrenocortical insufficiency is associated with HLA-related disorders including type 1 diabetes mellitus and autoimmune thyroid disease. Other less common related disorders include alopecia areata, vitiligo, primary hypogonadism, pernicious anemia, and celiac disease. This disorder is often referred to as APS type 2 (APS-2). The genetic susceptibility to this disorder is linked to HLA-DR3 or DR4 (or both). These patients have anti-adrenal cytoplasmic antibodies that may be important in the pathogenesis of this disorder, and autoantibodies directed against 21α-hydroxylase (P450c21, CYP21A2) have been identified (see Chapter 2).

B. Adrenal hemorrhage Bilateral adrenal hemorrhage is a rare cause of adrenal insufficiency. The diagnosis is generally made in ill patients with significant symptoms of adrenal dysfunction. However, in some cases the diagnosis is made only after a computed tomography (CT) scan of the abdomen reveals bilateral adrenal enlargement and leads to an assessment of adrenocortical function. Anatomic factors predispose the adrenal glands to hemorrhage. The adrenal glands have a rich arterial blood supply, but they are drained by a single vein. Adrenal vein thrombosis may occur during periods of stasis or turbulence, thereby increasing adrenal vein pressure and resulting in a *vascular dam*. This causes hemorrhage into the gland and is followed by adrenocortical insufficiency.

Most patients with adrenal hemorrhage have been taking anticoagulant therapy for an underlying coagulopathy or are predisposed to thrombosis. Heparin-induced thrombocytopenia syndrome may be accompanied by adrenal vein thrombosis and
FIGURE 9–8 Hypothalamic-pituitary axis in adrenal insufficiency of different causes. These panels illustrate hormone secretion in the normal state (upper left), primary adrenal insufficiency (upper right), secondary adrenal insufficiency—ACTH deficiency (lower left), and tertiary adrenal insufficiency—CRH deficiency (lower right). Renin-angiotensin system is also illustrated. In contrast to normal secretion and hormone levels, decreased hormonal secretion is indicated by a dotted line and increased secretion by a dark solid line.

TABLE 9–3 Causes of primary adrenocortical insufficiency.

Autoimmune
Metastatic malignancy or lymphoma
Adrenal hemorrhage
Coagulopathy
Antiphospholipid antibody syndrome
Infectious
    Tuberculosis, CMV, fungi (histoplasmosis, coccidioidomycosis), HIV
Adrenoleukodystrophy
Infiltrative disorders
    Amyloidosis, hemochromatosis
Congenital adrenal hyperplasia
Familial glucocorticoid deficiency and hypoplasia
Drugs
    Ketoconazole, metyrapone, aminoglutethimide, trilostane,
        mitotane, etomidate

hemorrhage. The primary antiphospholipid antibody syndrome (lupus anticoagulant) has emerged as one of the more common causes of adrenal hemorrhage.

C. Infections   Although tuberculosis is a common cause of primary adrenal insufficiency in the rest of the world, it is a rare cause of this problem in the United States. Clinically significant adrenal insufficiency appears to occur in only about 5% of patients with disseminated tuberculosis. With the use of antituberculous chemotherapy, it may even be reversible if detected in early stages. It is important to recognize that rifampin may accelerate the metabolic clearance of cortisol, thereby increasing the replacement dose needed in these patients. Most, if not all, systemic fungal infections can involve and destroy the adrenal cortex. Tuberculosis and fungal infections are associated with enlarged adrenals that may show calcifications. Of note, the azole antifungal agents, such as ketoconazole, inhibit adrenal cytochrome P450 steroidogenic enzymes that are essential for cortisol biosynthesis. Thus, azole antifungal treatment, especially with ketoconazole, in patients with marginal adrenocortical reserve due to fungal disease may precipitate adrenal crisis.

HIV/AIDS has been associated with pathologic involvement of the adrenal gland. Although adrenal necrosis is commonly seen in postmortem examination of patients with AIDS, primary adrenal insufficiency appears to develop in few patients with this disorder. Primary adrenal insufficiency in AIDS is usually caused by opportunistic infections such as fungal infection, cytomegalovirus, and mycobacterium avium complex. Adrenocortical insufficiency usually occurs as a late manifestation in AIDS patients with very low CD4 counts (see Chapter 25).

D. Adrenoleukodystrophy   X-linked adrenoleukodystrophy is an important cause of adrenal insufficiency in men. This disorder represents two distinct entities that may cause malfunction of the adrenal cortex and demyelination in the central nervous system. These disorders are characterized by abnormally high levels of very long chain fatty acids (VLCFAs) due to their defective beta oxidation within peroxisomes. The abnormal accumulation of VLCFAs in the brain, adrenal cortex, testes, and liver result in the clinical manifestations of this disorder.

Adrenoleukodystrophy has an incidence of approximately one in 25,000 and is an X-linked disorder (chromosome Xq28) with incomplete penetrance. Molecular analysis is available clinically and can be used both in family screening and in prenatal evaluation. Two clinical phenotypes have been described. Cerebral adrenoleukodystrophy usually presents in childhood, and its neurologic symptoms include cognitive dysfunction, behavioral problems, emotional lability, and visual and gait disturbances. It may progress to dementia. Because 30% of these patients develop adrenal insufficiency before the onset of neurologic symptoms, a young man with primary adrenal insufficiency should always be screened for adrenoleukodystrophy. A clinically milder phenotype, adrenomyeloneuropathy, usually presents in the second to fourth decades of life. Spinal cord and peripheral nerve demyelination occur over years and may result in loss of ambulation, cognitive dysfunction, urinary retention, and impotence. Once again, adrenal insufficiency may occur before the onset of neurologic symptoms.

The diagnosis of adrenoleukodystrophy can be confirmed by demonstration of the defect in fatty acid metabolism with the abnormal accumulation of saturated VLCFAs, especially C26:0 fatty acid.

E. Metastatic adrenal disease   The adrenal glands are common sites of metastasis for lung, gastrointestinal, melanoma, breast, and renal neoplasia. Bilateral adrenal involvement is present in approximately 50% of patients; however, adrenal insufficiency does not occur with unilateral metastatic disease. Even with bilateral involvement adrenal insufficiency appears to be uncommon. Despite being uncommon, patients with bilateral disease should be evaluated for adrenal insufficiency and then followed as adrenal insufficiency is a potentially life threating condition. In addition, non-Hodgkin and Hodgkin lymphoma may present with involvement of the adrenal glands with bilateral adrenal enlargement and primary adrenal insufficiency.

F. Familial glucocorticoid deficiency and congenital adrenal hypoplasia   Familial glucocorticoid deficiency is a very rare disorder in which there is hereditary adrenocortical unresponsiveness to ACTH. This leads to adrenal insufficiency with subnormal glucocorticoid and adrenal androgen secretion as well as elevated plasma ACTH levels. As a rule, aldosterone secretion is preserved. At least two distinct types of this disorder have been described. One type is associated with mutations in the ACTH receptor on the cells of the adrenal cortex. Another type is often associated with achalasia and alacrima (Allgrove syndrome; triple A syndrome) and progressive neurologic impairment, but no mutations in the ACTH receptor have been seen in these patients. Mutations in the AAAS gene on chromosome 12 (12q13) are responsible for this disorder as they encode a protein called ALADIN, whose function remains incompletely understood. Congenital adrenal hypoplasia is a developmental abnormality usually presenting in the neonatal period. X-linked

forms associated with mutations of DAX1 and autosomal recessive forms have been reported.

G. Cortisol resistance   Primary cortisol resistance is an unusual disorder representing target cell resistance to cortisol due to either qualitative or quantitative abnormalities of the glucocorticoid receptor. This disorder is characterized by hypercortisolism without clinical manifestations of glucocorticoid excess. Pituitary resistance to cortisol results in hypersecretion of ACTH, which stimulates the adrenal gland to produce excessive amounts of cortisol, mineralocorticoids, and adrenal androgens. The increased production of cortisol and these nonglucocorticoid adrenal steroids may cause hypertension, hypokalemia, virilization, and sexual precocity. Because cortisol is essential for life, this disorder actually represents partial rather than complete resistance.

H. Drug-induced adrenal insufficiency   Drugs associated with primary adrenal insufficiency include the azole antifungal agents, the anesthetic agent etomidate, the antiparasitic agent suramin as well as the steroid synthesis inhibitors aminoglutethimide, metyrapone, and mitotane. Mifepristone is a progesterone antagonist that also antagonizes the glucocorticoid receptor and may cause adrenal insufficiency if given in sufficient doses. Megestrol acetate, a synthetic progesterone derivative used to stimulate appetite, binds to the glucocorticoid receptor and suppresses the HPA axis leading to adrenal insufficiency after withdrawal of therapy. Opioid narcotics cause a transient suppression of the HPA axis and can lead to suppression of plasma cortisol levels. Additionally, the use of protease inhibitors with exogenous glucocorticoids (from oral, injectable, inhaled, or even optic routes) can cause secondary adrenal insufficiency after cessation of glucocorticoid use. The immune checkpoint inhibitors are also well described to cause an array of autoimmune conditions including ACTH deficiency and secondary adrenal insufficiency.

I. Cortisol in critical illness   In 2002 it was reported that 77% of 299 patients with severe sepsis had plasma cortisol increments of less than 9 μg/dL after standard ACTH stimulation testing. These patients were classified as having *relative adrenal insufficiency* (also termed *partial adrenal insufficiency* or *decreased adrenal reserve*) and randomized to therapy with hydrocortisone and fludrocortisones with a modest survival benefit. The study led to a widespread recommendation that all severely ill patients with sepsis be tested with ACTH and treated with corticosteroids. However, the study was compromised by two major issues. First, 30% of the patients classified as relatively adrenal insufficient had received etomidate (a drug which causes adrenal insufficiency) within 12 hours of enrollment. Second, the authors did not recognize that total plasma cortisol levels and their response to ACTH are lowered in severely ill patients who frequently have hypoalbuminemia and low corticosteroid-binding globulin levels. Subsequent studies have shown that both plasma free cortisol and salivary cortisol are appropriately elevated and respond normally to ACTH in patients with sepsis. In addition, several studies have shown no survival benefit following corticosteroid therapy. Thus, there is

no convincing evidence that adrenal insufficiency is frequent in critically ill patients.

Pathophysiology

Loss of more than 90% of both adrenal cortices results in the clinical manifestations of adrenocortical insufficiency. Gradual destruction, such as occurs in the idiopathic and invasive forms of the disease, leads to chronic adrenocortical insufficiency. However, more rapid destruction occurs in many cases; about 25% of patients are in crisis or impending crisis at the time of diagnosis. With gradual adrenocortical destruction, the initial phase is that of decreased adrenal reserve; that is, basal steroid secretion is normal, but secretion does not increase in response to stress. Thus, acute adrenal crisis can be precipitated by the stresses of surgery, trauma, or infection, which require increased corticosteroid secretion. With further loss of cortical tissue, even basal secretion of glucocorticoids becomes deficient, leading to the manifestations of chronic adrenocortical insufficiency. Mineralocorticoid deficiency may occur early or late in the course. Destruction of the adrenals by hemorrhage results in sudden loss of both glucocorticoid and mineralocorticoid secretion, accompanied by acute adrenal crisis.

With decreasing cortisol secretion, plasma levels of ACTH are increased because of decreased negative feedback inhibition of their secretion. In fact, an elevation of plasma ACTH may be the earliest and most sensitive indication of suboptimal adrenocortical reserve.

Clinical Features

A. Symptoms and signs   Cortisol deficiency causes weakness, fatigue, anorexia, nausea and vomiting, hypotension, hyponatremia, and hypoglycemia. Mineralocorticoid deficiency produces renal sodium wasting and potassium retention and can lead to severe dehydration, hypotension, hyponatremia, hyperkalemia, and acidosis.

1. **Chronic primary adrenocortical insufficiency**—The chief symptoms (Table 9–4) are hyperpigmentation, weakness and fatigue, weight loss, anorexia, and gastrointestinal disturbances.
   Hyperpigmentation is the classic physical finding, and its presence in association with the above manifestations should suggest primary adrenocortical insufficiency. Generalized hyperpigmentation of the skin and mucous membranes is one of the earliest manifestations of Addison disease. It is increased

TABLE 9–4   Clinical features of primary adrenocortical insufficiency.

	Frequency
Weakness, fatigue, anorexia, weight loss	Universal
Hyperpigmentation	Universal
Hypotension	Very common
Gastrointestinal disturbances	Very common
Salt craving	Frequent
Postural symptoms	Infrequent
	Infrequent

in sun-exposed areas and accentuated over pressure areas such as the knuckles, toes, elbows, and knees. It is accompanied by increased numbers of black or dark-brown freckles. The classic hyperpigmentation of the buccal mucosa and gums is preceded by generalized hyperpigmentation of the skin; adrenal insufficiency should also be suspected when there is increased pigmentation of the palmar creases, nail beds, nipples, areolae, and perivaginal and perianal mucosa. Scars that have formed after the onset of ACTH excess become hyperpigmented, whereas older ones do not.

General weakness, fatigue and malaise, anorexia, and weight loss are invariable features of the disorder. Weight loss may reach 15 kg with progressive adrenal failure. Gastrointestinal disturbances, especially nausea and vomiting, occur in most patients; diarrhea is less frequent. An increase in gastrointestinal symptoms during an acute adrenal crisis may confuse the diagnosis by suggesting a primary intra-abdominal process.

Hypotension is present in about 90% of patients and is accompanied by orthostatic symptoms and occasionally syncope. In more severe chronic cases and in acute crises, recumbent hypotension or shock is almost invariably present. Vitiligo occurs in 4% to 17% of patients with autoimmune Addison disease but is rare in Addison disease due to other causes. Salt craving occurs in about 20% of patients.

Severe hypoglycemia may occur in children. This finding is unusual in adults but may be provoked by fasting, fever, infection, or nausea and vomiting, especially in acute adrenal crisis. Hypoglycemia occurs more commonly in secondary adrenal insufficiency.

Amenorrhea is common in Addison disease. It may be due to weight loss and chronic illness or to primary ovarian failure. Loss of axillary and pubic hair may occur in women as a result of decreased secretion of adrenal androgens.

Partial adrenal insufficiency may have subtle clinical manifestations. Adrenal insufficiency should be considered in the differential diagnosis of unexplained weight loss and in patients with hypotension and fever.

2. **Acute adrenal crisis**—Acute adrenal crisis represents a state of acute adrenocortical insufficiency and occurs in patients with Addison disease who are exposed to the stress of infection, trauma, surgery, or dehydration due to salt deprivation, vomiting, or diarrhea.

The symptoms are listed in Table 9–5. Anorexia and nausea and vomiting increase and worsen the volume depletion and dehydration. Hypovolemic shock frequently occurs, and adrenal insufficiency should be considered in any patient with unexplained vascular collapse. Abdominal pain may occur and mimic an acute abdominal emergency. Weakness, apathy, and confusion are common. Fever is also common and may be due to infection or to hypoadrenalism per se. Hyperpigmentation is present unless the onset of adrenal insufficiency is rapid and should suggest the diagnosis.

Additional findings that suggest the diagnosis are hyponatremia, hyperkalemia, lymphocytosis, eosinophilia, and hypoglycemia.

Shock and coma may rapidly lead to death in untreated patients (see Chapter 24).

3. **Acute adrenal hemorrhage (Table 9–6)**—Bilateral adrenal hemorrhage and acute adrenal destruction in an already compromised patient with major medical illness follow a progressively deteriorating course. The usual manifestations are abdominal, flank, or back pain and abdominal tenderness. Abdominal distention, rigidity, and rebound tenderness are less frequent. Hypotension, shock, fever, nausea and vomiting, confusion, and disorientation are common; tachycardia and cyanosis are less frequent.

With progression, severe hypotension, volume depletion, dehydration, hyperpyrexia, cyanosis, coma, and death ensue.

The diagnosis of acute adrenal hemorrhage should be considered in the deteriorating patient with unexplained abdominal or flank pain, vascular collapse, hyperpyrexia, or hypoglycemia, particularly in the setting of an underlying coagulopathy.

B. Laboratory and electrocardiographic findings and imaging studies

1. **Gradual adrenal destruction**—Hyponatremia and hyperkalemia are classic manifestations of the glucocorticoid and mineralocorticoid deficiency of primary adrenal insufficiency and should suggest the diagnosis. Hematologic manifestations include normocytic, normochromic anemia, neutropenia, eosinophilia, and a relative lymphocytosis. Azotemia with increased concentrations of blood urea nitrogen and serum creatinine is due to volume depletion and dehydration. Mild acidosis is frequently present. Hypercalcemia of mild to moderate degree occurs in about 6% of patients.

Abdominal radiographs reveal adrenal calcification in half the patients with tuberculous Addison disease and in some patients with other invasive or hemorrhagic causes of adrenal insufficiency. CT is a more sensitive detector of adrenal calcification and adrenal enlargement. Bilateral adrenal enlargement in association with adrenal insufficiency may be seen with tuberculosis, fungal infections, cytomegalovirus, malignant and nonmalignant infiltrative diseases, and adrenal hemorrhage.

Electrocardiographic features show low voltage, a vertical QRS axis, and nonspecific ST-T wave abnormalities secondary to abnormal electrolytes.

2. **Acute adrenal hemorrhage**—Hyponatremia and hyperkalemia occur in only a small number of cases, but azotemia is a common finding. Increased circulating eosinophils may suggest the diagnosis. The diagnosis is frequently established only when imaging studies reveal bilateral adrenal enlargement.

SECONDARY ADRENOCORTICAL INSUFFICIENCY

Etiology

Secondary adrenocortical insufficiency due to ACTH deficiency is most commonly a result of exogenous glucocorticoid therapy. Pituitary or hypothalamic tumors, and their treatment, are the most common causes of naturally occurring pituitary ACTH hyposecretion. These and other less common causes are reviewed in Chapter 4.

Pathophysiology

ACTH deficiency is the primary event and leads to decreased cortisol and adrenal androgen secretion. Aldosterone secretion almost always remains normal as renin continues to stimulate aldosterone production. In the early stages, basal ACTH and cortisol levels may be normal; however, ACTH reserve is impaired, and ACTH and cortisol responses to stress are, therefore, subnormal. With further loss of basal ACTH secretion, there is atrophy of the zonae fasciculata and reticularis of the adrenal cortex; and, therefore, basal cortisol secretion is decreased. At this stage, the entire pituitary adrenal axis is impaired; that is, there is not only decreased ACTH responsiveness to stress but also decreased adrenal responsiveness to acute stimulation with exogenous ACTH.

The manifestations of glucocorticoid deficiency are similar to those described for primary adrenocortical insufficiency. However, because aldosterone secretion by the zona glomerulosa is usually preserved, the manifestations of mineralocorticoid deficiency are absent.

Clinical Features

A. Symptoms and signs   Secondary adrenal insufficiency is usually chronic, and the manifestations may be nonspecific. However, acute crisis can occur in undiagnosed patients or in corticosteroid-treated patients who do not receive increased steroid dosage during periods of stress.

The clinical features of secondary adrenal insufficiency differ from those of primary adrenocortical insufficiency, in that pituitary secretion of ACTH is deficient, and hyperpigmentation is, therefore, not present. In addition, mineralocorticoid secretion is usually normal. Thus, the clinical features of ACTH and glucocorticoid deficiency are nonspecific.

Volume depletion, dehydration, and hyperkalemia are usually absent. Hypotension is usually not present except in acute presentations. Hyponatremia may occur, as a result of water retention

and inability to excrete a water load, but is not accompanied by hyperkalemia. Prominent features are weakness, lethargy, easy fatigability, anorexia, nausea, and occasionally vomiting. Arthralgias and myalgias also occur. Hypoglycemia is occasionally the presenting feature. Acute decompensation with severe hypotension or shock unresponsive to vasopressors may occur.

B. Associated features   Patients with secondary adrenal insufficiency commonly have additional features that suggest the diagnosis. A history of glucocorticoid therapy, or if this is not available, the presence of Cushingoid features suggests prior glucocorticoid use. Hypothalamic or pituitary tumors leading to ACTH deficiency usually cause loss of other pituitary hormones (hypogonadism and hypothyroidism). Hypersecretion of GH or prolactin (PRL) from a pituitary adenoma may be present.

C. Laboratory findings   Findings on routine laboratory examination consist of normochromic, normocytic anemia, neutropenia, lymphocytosis, and eosinophilia. Hyponatremia is not uncommon and may be the presenting laboratory abnormality. Hyponatremia is due to the lack of glucocorticoid-negative feedback on AVP as well as the reduction in glomerular filtration associated with hypocortisolism. Serum potassium, creatinine, and bicarbonate and blood urea nitrogen are usually normal; plasma glucose may be low, although severe hypoglycemia is unusual.

DIAGNOSIS OF ADRENOCORTICAL INSUFFICIENCY

Although the diagnosis of adrenal insufficiency should be confirmed by assessment of the pituitary adrenal axis, therapy should not be delayed, and the patient should not be subjected to procedures that may increase volume loss and dehydration and further contribute to hypotension. If the patient is acutely ill, therapy should be instituted and the diagnosis established when the patient is stable.

Diagnostic Tests

Because basal levels of adrenocortical steroids in either urine or plasma may be normal in partial adrenal insufficiency, tests of adrenocortical reserve are necessary to establish the diagnosis (Figure 9–9). These tests are described in the section on laboratory evaluation and in Chapter 4.

Rapid ACTH Stimulation Test

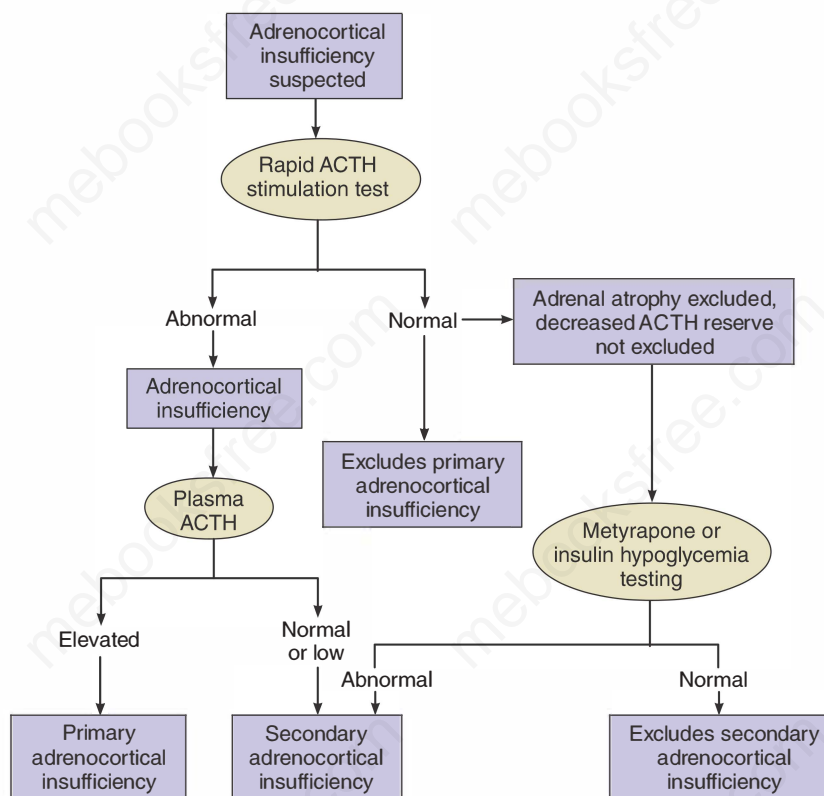
The rapid ACTH stimulation test assesses adrenal reserve and is the initial procedure in the assessment of possible adrenal insufficiency, either primary or secondary. As previously discussed, the low-dose ACTH (1-μg cosyntropin) stimulation test has been suggested to represent a more physiologic stimulus to the adrenal cortex; however, evidence-based guidelines for the diagnosis of adrenal insufficiency suggest that the standard 250 μg cosyntropin dose provides the best diagnostic certainty, and the low-dose


FIGURE 9–9 Evaluation of suspected primary or secondary adrenocortical insufficiency. Boxes enclose clinical decisions, and circles enclose diagnostic tests. (Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism*. 3rd ed. New York: McGraw-Hill Education; 1995.)

(1 μg) test should be reserved for centers with well-validated normal controls and extensive clinical experience.

Subnormal responses to exogenous ACTH administration are an indication of decreased adrenal reserve and establish the diagnosis of adrenocortical insufficiency. Further diagnostic procedures are not required, because subnormal responses to the rapid ACTH stimulation test indicate lack of responsiveness to metyrapone, insulin-induced hypoglycemia, or stress. However, this test does not permit differentiation of primary and secondary causes. This is best accomplished by measurement of basal plasma ACTH levels, as discussed later.

A normal response to the rapid ACTH stimulation test excludes primary adrenal failure, because a normal cortisol response indicates normal cortical function. However, normal responsiveness does not exclude partial secondary adrenocortical insufficiency in those few patients with decreased pituitary reserve and decreased stress responsiveness of the HPA axis who maintain sufficient basal ACTH secretion to prevent adrenocortical atrophy. If this situation is suspected clinically, pituitary ACTH responsiveness may be tested directly with metyrapone, CRH stimulation, or insulin-induced hypoglycemia (see section "Laboratory Evaluation" and Table 9–7).

TABLE 9–7 ACTH and cortisol response in adrenal insufficiency of varying etiologies.

	Basal State		Response to CRH Infusion	
	ACTH	**Cortisol**	**ACTH**	**Cortisol**
Normal Adrenal Function	Normal	Normal	Significant Increase	Significant Increase
Acute Primary AI	Very High	Low	Increase	No Change
Chronic Primary AI	Very High	Low	Increase	No Change
Acute Secondary AI	Normal to Low	Low	No Change or Small Increase	No Change or Small Increase
Chronic Secondary AI	Low	Low	No Change	No Change

Plasma ACTH Levels

If adrenal insufficiency is present, plasma ACTH levels are used to differentiate primary and secondary forms. In patients with primary adrenal insufficiency, plasma ACTH levels exceed the upper limit of the reference range (>52 pg/mL [11 pmol/L]) and usually exceed 200 pg/mL (44 pmol/L). Plasma ACTH concentrations are inappropriately normal or less than 10 pg/mL (2.2 pmol/L) in patients with secondary adrenal insufficiency (see Figure 9–9). However, basal ACTH levels must always be interpreted in light of the clinical situation, especially because of the episodic nature of ACTH secretion and its short plasma half-life. For example, ACTH levels frequently exceed the normal range during the recovery of the HPA axis from secondary adrenal insufficiency and may be confused with levels seen in primary adrenal insufficiency. Patients with primary adrenal insufficiency consistently have elevated ACTH levels. In fact, the ACTH concentration is elevated early in the course of adrenal insufficiency before a significant reduction in the basal cortisol level or its response to exogenous ACTH occurs. Therefore, plasma ACTH measurements serve as a valuable screening study for primary adrenal insufficiency.

Partial ACTH Deficiency

When partial ACTH deficiency and decreased pituitary reserve are suspected despite normal responsiveness to the rapid ACTH stimulation test, the following procedures may be used for more direct assessment of hypothalamic-pituitary function.

A. Methods of testing   The overnight metyrapone test is used in patients with suspected hypothalamic or pituitary disorders when hypoglycemia is contraindicated and in those with prior glucocorticoid therapy. Insulin-induced hypoglycemia is used in patients with suspected hypothalamic or pituitary tumors, because both ACTH and GH responsiveness can be assessed (see Chapter 4).

B. Interpretation   A normal response to either metyrapone or hypoglycemia excludes secondary adrenocortical insufficiency (see section "Laboratory Evaluation"). Subnormal responses, even in the presence of a normal response to ACTH administration, establish the diagnosis of secondary adrenal insufficiency.

TREATMENT OF ADRENOCORTICAL INSUFFICIENCY

The aim of treatment of adrenocortical insufficiency is to produce levels of glucocorticoids and mineralocorticoids equivalent to those achieved in an individual with normal HPA function under similar circumstances.

Acute Addisonian Crisis (Table 9–8)

Treatment for acute Addisonian crisis should be instituted as soon as the diagnosis is suspected and not delayed until the diagnosis is

TABLE 9–8   Treatment of acute adrenal crisis.

Glucocorticoid Replacement
(1) Administer hydrocortisone sodium phosphate or sodium succinate, 50-100 mg intravenously every 6-12 h for 24 h
(2) When the patient is stable, reduce the dosage by 50%
(3) Taper to maintenance therapy on day 3-5 and add mineralocorticoid therapy as required

General and Supportive Measures
(1) Correct volume depletion, dehydration, and hypoglycemia with intravenous saline and glucose
(2) Evaluate and correct infection and other precipitating factors

confirmed. Therapy includes administration of glucocorticoids; correction of dehydration, hypovolemia, and electrolyte abnormalities; general supportive measures; and treatment of coexisting or precipitating disorders.

A. Cortisol (Hydrocortisone)   Parenteral cortisol in soluble form (hydrocortisone hemisuccinate or phosphate) is the glucocorticoid preparation most commonly used. When administered in supraphysiologic doses, hydrocortisone has sufficient sodium-retaining potency so that additional mineralocorticoid therapy is not required in patients with primary adrenocortical insufficiency.

Cortisol in intravenous doses of 50 to 100 mg is given every 6 to 12 hours for the first 24 hours. The response to therapy is usually rapid, with improvement occurring within 12 hours or less. If improvement occurs and the patient is stable, doses can be weaned by 50% on the second day, and in most patients the dosage may then be gradually reduced to maintenance dose thereafter (see section "Maintenance Therapy," later).

1. In severely ill patients, especially in those with additional major complications (eg, sepsis), higher cortisol doses (100 mg intravenously every 6-8 hours) are maintained until the patient is stable.
2. In primary Addison disease, mineralocorticoid replacement, in the form of fludrocortisone (see later), is usually added when hydrocortisone replacement is reduced to near physiological levels.
3. In secondary adrenocortical insufficiency with acute crisis, the primary requirement is glucocorticoid replacement and is satisfactorily supplied by the administration of cortisol, as outlined earlier. If the possibility of excessive fluid and sodium retention in such patients is of concern, equivalent parenteral doses of synthetic steroids such as prednisolone or dexamethasone may be substituted.

B. Intravenous fluids   Intravenous glucose and saline are administered to correct volume depletion, hypotension, and hypoglycemia. Volume deficits may be severe in Addison disease, and hypotension and shock may not respond to vasopressors unless glucocorticoids are administered. Hyperkalemia and acidosis are usually corrected with cortisol and volume replacement; however, an occasional patient may require specific therapy for these abnormalities (see also Chapter 24).

TABLE 9–9 **Regimen for maintenance therapy of primary adrenocortical insufficiency.**

(1) Hydrocortisone, 10-15 mg in AM, 5-10 mg in the afternoon (4-5 PM)

(2) Fludrocortisone, 0.05-0.1 mg orally in AM

(3) Clinical follow-up: maintenance of normal weight, blood pressure, and electrolytes with regression of clinical features

(4) Patient education plus identification card, medical alert bracelet or necklace (*dog tag*). Useful patient education materials are available from the National Institutes of Health. http://www.cc.nih.gov/ccc/patient_education/pepubs/mngadrins.pdf

(5) Increase hydrocortisone dosage during stress. Double or triple the oral dose for mild illness. Provide patient with injectable form of glucocorticoid for emergency use

Maintenance Therapy (Table 9–9)

Patients with Addison disease require life-long glucocorticoid and mineralocorticoid therapy. Cortisol (hydrocortisone) is the glucocorticoid preparation of choice. The basal production rate of cortisol is approximately 8 to 12 mg/m^2/d. The maintenance dose of hydrocortisone is usually 15 to 25 mg daily in adults. The oral dose is usually divided into 10 to 15 mg in the morning on arising and 5 to 10 mg later in the day. Cortisol in twice-daily doses gives satisfactory responses in most patients; however, some patients may require only a single morning dose, and others may require three doses daily (eg, 10-5-5) to maintain well-being and normal energy levels. Insomnia is a side-effect of glucocorticoid administration and can usually be prevented by administering the last dose in the early afternoon.

Fludrocortisone (9α-fluorocortisol) is used for mineralocorticoid therapy; the usual doses are 0.05 to 0.2 mg/d orally in the morning. Because of the long half-life of this agent, divided doses are not required. About 10% of addisonian patients can be managed with cortisol and adequate dietary sodium intake alone and do not require fludrocortisone.

Secondary adrenocortical insufficiency is treated with the cortisol dosages described earlier for the primary form. Fludrocortisone is rarely required. The recovery of normal function of the HPA axis following suppression by exogenous glucocorticoids may take weeks to years, and its duration is not readily predictable. Consequently, prolonged replacement therapy may be required. Several studies in women have suggested potential benefits of DHEA in doses of 50 mg/d in terms of improvement in well-being, although this remains controversial.

Response to Therapy

General clinical signs, such as good appetite and sense of well-being, are the guides to the adequacy of replacement. Obviously, signs of Cushing syndrome indicate overtreatment. It is generally expected that the daily dose of hydrocortisone should be doubled or tripled during periods of minor stress, and the dose needs to be increased to as much as 200 to 300 mg/d during periods of major stress, such as a surgical procedure. Acute adrenal crisis is a common problem in patients with established adrenal insufficiency (8%-10% per year); accordingly, appropriate sick day

management with stress dosing of glucocorticoids should be reinforced frequently. Patients receiving excessive doses of glucocorticoids are also at risk for increased bone loss and clinically significant osteoporosis. Therefore, the replacement dose of glucocorticoid should be maintained at the lowest amount needed to provide the patient with a proper sense of well-being. Two major factors have prompted a reassessment of the issue of appropriateness and possible excess glucocorticoid replacement for patients with adrenal insufficiency. First, there is a greater appreciation of the potential risks of overtreatment or undertreatment. Recent evidence suggests that subclinical Cushing syndrome associated with adrenal incidentaloma contributes to elevated blood sugar and blood pressure, decreased bone mineral density, increased cardiovascular disease, and even increased mortality. The levels of cortisol secretion by many incidentalomas are similar to those observed in patients with adrenal insufficiency receiving mild cortisol overreplacement. In addition, studies in patients receiving glucocorticoid replacement therapy demonstrate an inverse relationship between dose and bone mineral density and a positive correlation between dose and markers of bone resorption. Second, there is recognition that there is considerable variation among individuals in terms of the plasma levels of cortisol achieved with orally administered hydrocortisone or cortisol.

The measurement of urine free cortisol does not provide a reliable index for appropriate glucocorticoid replacement. Similarly, ACTH measurements are not a good indication of the adequacy of glucocorticoid replacement; marked elevations of plasma ACTH in patients with chronic adrenal insufficiency are often not suppressed into the normal range despite adequate hydrocortisone replacement. In fact, plasma ACTH values that fall to low normal or low levels suggest overreplacement with glucocorticoids. Plasma cortisol day curves—multiple samples for plasma cortisol concentration—have been proposed but not yet widely adopted. Therefore, it is prudent to use clinical assessment of the patient's response to therapy, rather than biochemical criteria, to gauge the adequacy of steroid replacement.

Adequate treatment results in the disappearance of weakness, malaise, and fatigue. Anorexia and other gastrointestinal symptoms resolve, and weight returns to normal. The hyperpigmentation invariably improves but may not entirely disappear. Inadequate cortisol administration leads to persistence of these symptoms of adrenal insufficiency, and excessive pigmentation remains.

Adequate mineralocorticoid replacement may be determined by assessment of blood pressure and electrolyte composition. With adequate treatment, the blood pressure is normal without orthostatic change, and serum sodium and potassium remain within the normal range. Some endocrinologists monitor plasma renin activity (PRA) as an objective measure of fludrocortisone replacement. Upright PRA levels are usually less than 5 ng/mL/h in adequately replaced patients. Hypertension and hypokalemia result if the fludrocortisone dose is excessive. Conversely, undertreatment may lead to fatigue and malaise, orthostatic symptoms, and subnormal supine or upright blood pressure, with hyperkalemia and hyponatremia.

Prevention of Adrenal Crisis

The development of acute adrenal insufficiency in previously diagnosed and treated patients is almost entirely preventable in compliant individuals. The essential elements are patient education and increased glucocorticoid dosages during illness.

The patient should be informed about the necessity for lifelong therapy, the possible consequences of acute illness, and the necessity for increased therapy and medical assistance during acute illness. An identification card or bracelet should be carried or worn at all times.

The cortisol dose should be increased by the patient to 60 to 80 mg/d with the development of minor illnesses; the usual maintenance dosage may be resumed in 24 to 48 hours if improvement occurs. Increased mineralocorticoid therapy is not required.

If symptoms persist or become worse, the patient should continue increased cortisol doses and call the physician.

Vomiting may result in inability to ingest or absorb oral cortisol, and diarrhea in addisonian patients may precipitate a crisis because of rapid fluid and electrolyte losses. Patients must understand that if these symptoms occur, they should seek immediate medical assistance so that parenteral glucocorticoid therapy can be given.

Steroid Coverage for Surgery (Table 9–10)

The normal physiologic response to surgical stress involves an increase in cortisol secretion. The increased glucocorticoid activity may serve primarily to modulate the immunologic response to stress. Thus, patients with primary or secondary adrenocortical insufficiency scheduled for elective surgery require increased glucocorticoid coverage. This problem is most frequently encountered in patients with pituitary-adrenal suppression due to exogenous glucocorticoid therapy. The principles of management are outlined in Table 9–10.

PROGNOSIS OF ADRENOCORTICAL INSUFFICIENCY

Before glucocorticoid and mineralocorticoid therapy became available, primary adrenocortical insufficiency was invariably fatal, with death usually occurring within 2 years after onset. Survival

TABLE 9–10 **Steroid coverage for surgery.**

(1) Correct electrolytes, blood pressure, and hydration if necessary

(2) Give hydrocortisone sodium phosphate or sodium succinate, 100 mg intramuscularly, on call to operating room

(3) Give 50 mg intramuscularly or intravenously in the recovery room and then every 6-8 h for the first 24 h

(4) If progress is satisfactory, reduce dosage to 25 mg every 6-8 h for 24 h and then taper to maintenance dosage over 2-5 d. Resume previous fludrocortisone dose when the patient is taking oral medications

(5) Maintain or increase hydrocortisone dosage to 200-400 mg/d if fever, hypotension, or other complications occur

Reproduced with permission from Felig P, Baxter JD, Frohman LA. *Endocrinology and Metabolism.* 3rd ed. New York: McGraw-Hill Education; 1995.

now depends on the underlying cause of the adrenal insufficiency. In patients with autoimmune Addison disease, survival approaches that of the normal population, and most patients lead normal lives. In general, death from adrenal insufficiency now occurs only in patients with rapid onset of disease who may die before the diagnosis is established and appropriate therapy started.

Secondary adrenal insufficiency has an excellent prognosis with glucocorticoid therapy. Adrenal insufficiency due to bilateral adrenal hemorrhage may be fatal, with some cases being recognized only at autopsy.

CUSHING SYNDROME

Chronic glucocorticoid excess, whatever its cause, leads to the constellation of symptoms and physical features known as **Cushing syndrome**. It is most commonly iatrogenic, resulting from chronic glucocorticoid therapy. Spontaneous Cushing syndrome is caused by abnormalities of the pituitary or adrenal gland or may occur as a consequence of ACTH or CRH secretion by nonpituitary tumors (**ectopic ACTH syndrome; ectopic CRH syndrome**) (Figure 9–10). **Cushing disease** is defined as the specific type of Cushing syndrome due to excessive pituitary ACTH secretion from a pituitary tumor. This section reviews the various types of endogenous Cushing syndrome and discuss their diagnosis and therapy (see also Chapter 4).

Classification and Incidence

Cushing syndrome is classified as either ACTH dependent or ACTH independent (Table 9–11). The ACTH-dependent types of Cushing syndrome—ectopic ACTH syndrome and Cushing disease—are characterized by chronic ACTH hypersecretion, which results in hyperplasia of the adrenal zonae fasciculata and reticularis and, therefore, increased secretion of cortisol, androgens, and DOC.

ACTH-independent Cushing syndrome may be caused by a primary adrenal neoplasm (adenoma or carcinoma) or bilateral nodular adrenal hyperplasia. In these cases, the cortisol excess suppresses pituitary ACTH secretion.

A. Cushing disease   Traditionally this has been the most frequent type of Cushing syndrome and most studies attribute 80% of reported cases to Cushing disease. It is much more common in women than in men (female-male ratio of about 5:1) and the age at diagnosis is usually 20 to 40 years but may range from childhood to 70 years.

B. Ectopic ACTH hypersecretion   This disorder accounts for approximately 10% of patients with ACTH-dependent Cushing syndrome. The production of ACTH from a tumor of nonpituitary origin may result in severe hypercortisolism, but many of these patients lack the classic features of glucocorticoid excess. This presumably reflects the acuteness of the clinical course in the ectopic ACTH syndrome. The clinical
FIGURE 9–10 Hypothalamic-pituitary axis in Cushing syndrome of different causes. These panels illustrate hormone secretion in the normal state (upper left), and four types of cortisol excess: Pituitary ACTH-dependent (with an ACTH-secreting pituitary tumor) (upper right), adrenal tumor (lower left), ectopic ACTH syndrome due to an ACTH-secreting lung cancer (lower middle), and ectopic CRH syndrome due to a CRH-secreting lung tumor. In contrast to normal secretion and hormone levels, decreased hormonal secretion is indicated by a dotted line and increased secretion by a dark solid line.

presentation of ectopic ACTH secretion is most frequently seen in patients with tumors of a thoracic origin. Bronchial carcinoid, small cell and non-small cell lung carcinoma are responsible for over 50% of cases of this syndrome. The prognosis in patients with the ectopic ACTH syndrome is generally poor and largely a function of the primary tumor. Individuals with ectopic ACTH syndrome from small cell lung carcinoma have a mean survival of less than 12 months. The ectopic ACTH syndrome may also present in a fashion identical to classic Cushing disease and pose a challenging diagnostic dilemma. A wide

variety of tumors has been reported to produce ectopic ACTH and may be radiologically inapparent at the time of the presentation. The ectopic ACTH syndrome is more common in men, and the peak age incidence is 40 to 60 years.

C. Primary adrenal tumors   Primary adrenal tumors are increasingly being recognized as a common cause of Cushing syndrome. Most of these patients have benign adrenocortical adenomas. Adrenocortical carcinomas are uncommon, with an incidence of approximately 2 per million per year. Adrenal

TABLE 9–11 Cushing syndrome: differential diagnosis.

ACTH-Dependent
Pituitary adenoma (Cushing disease)
Nonpituitary neoplasm (ectopic ACTH)
ACTH-Independent
Iatrogenic (glucocorticoid, megestrol acetate)
Adrenal carcinoma
Unilateral adrenal neoplasm/adenoma
Bilateral adrenal hyperplasia/neoplasm
Bilateral macronodular adrenal hyperplasia
McCune Albright syndrome
Primary pigmented nodular adrenal disease
Isolated micronodular adrenocortical disease

carcinomas are more common in women. Autonomous cortisol secretion without the classic features of Cushing syndrome occurs in up to 20% to 25% of patients with adrenal incidentalomas (see later).

D. Childhood Cushing syndrome   Childhood Cushing disease is rare, but is more common in the adolescent population than in younger children. Most pediatric cases occur in patients over 10 years of age with an equal distribution between the sexes. Cushing disease remains the most common cause of Cushing syndrome accounting for more than 80% of cases. Primary adrenal disease accounts for an additional 10% to 15% of all pediatric cases. A hallmark of childhood Cushing syndrome is significant weight gain without accompanying linear growth.

Pathology

A. Anterior pituitary gland

1. **Pituitary adenomas**—Pituitary adenomas are present in over 90% of patients with Cushing disease. These tumors are typically smaller than those secreting GH or PRL; 80% to 90% are less than 10 mm in diameter. A small group of patients have larger tumors (>10 mm); these macroadenomas are frequently invasive, leading to extension outside the sella turcica. Malignant pituitary tumors occur very rarely.

   Microadenomas are located within the anterior pituitary; they are not encapsulated but surrounded by a rim of compressed normal anterior pituitary cells. With routine histologic stains, these tumors are composed of compact sheets of well-granulated basophilic cells in a sinusoidal arrangement. ACTH, β-lipotropin, and β-endorphin have been demonstrated in these tumor cells by immunocytochemical methods. Larger tumors may appear chromophobic on routine histologic study; however, they also contain ACTH and its related peptides. These ACTH-secreting adenomas typically show Crooke changes (a zone of perinuclear hyalinization that is the result of chronic exposure of corticotroph cells to hypercortisolism). Electron microscopy demonstrates secretory granules that vary in size from 200 to 700 nm. The number of granules varies in individual cells; they may be dispersed throughout the cytoplasm or concentrated along the cell membrane. A typical feature of these adenomas is the presence of bundles of perinuclear microfilaments (average 7 nm in diameter)

surrounding the nucleus; these are responsible for Crooke hyaline changes visible on light microscopy.

2. **Hyperplasia**—Diffuse hyperplasia of corticotroph cells has been reported rarely in patients with Cushing disease.

3. **Other conditions**—In patients with adrenal tumors or ectopic ACTH syndrome, the pituitary corticotrophs show prominent Crooke hyaline changes and perinuclear microfilaments. The ACTH content of corticotroph cells is reduced consistent with their suppression by excessive cortisol secretion present in these conditions.

B. Adrenocortical hyperplasia

Chronic ACTH hypersecretion, usually due to Cushing disease, can lead to bilateral enlargement and hyperplasia of the adrenal cortex. Combined adrenal weight (normal, 8-10 g) is modestly increased, ranging from 12 to 24 g. On histologic study, there is equal hyperplasia of the compact cells of the zona reticularis and the clear cells of the zona fasciculata; consequently, the width of the cortex is increased. Electron microscopy reveals normal ultrastructural features. When ACTH levels are very high as in the ectopic ACTH syndrome, the adrenals are frequently larger, with combined weights up to or more than 50 g. The characteristic microscopic feature is marked hyperplasia of the zona reticularis; columns of compact reticularis cells expand throughout the zona fasciculata and into the zona glomerulosa. The zona fasciculata clear cells are markedly reduced.

C. Nodular adrenal disease

Adrenal nodules that hypersecrete cortisol can be unilateral or bilateral, and their pathology varies depending on the etiology.

1. **Unilateral cortisol-secreting adrenal adenomas**—These adenomas are encapsulated, usually weigh 10 to 70 g, and range in size from 1 to 6 cm. Microscopically, clear cells of the zona fasciculata type predominate, although cells typical of the zona reticularis are also seen. The uninvolved adrenal cortex contiguous to the tumor and that of the contralateral gland are atrophic in the presence of functioning adrenal adenomas and carcinomas (see later). The cortex is markedly thinned, whereas the capsule is thickened. Histologically, the zona reticularis is virtually absent; the remaining cortex is composed of clear fasciculata cells. The architecture of the zona glomerulosa is normal.

2. **Adrenal carcinomas**—Adrenal carcinomas are usually greater than 4 cm when diagnosed and often weigh more than 100 g, occasionally exceeding 1 kg. They may be palpable as abdominal masses. Grossly, they are encapsulated and highly vascular; necrosis, hemorrhage, and cystic degeneration are common, and areas of calcification may be present. The histologic appearance of these carcinomas varies considerably; they may appear to be benign or may exhibit considerable pleomorphism. Vascular or capsular invasion is predictive of malignant behavior, as is local extension. These carcinomas invade local structures (kidney, liver, and retroperitoneum) and metastasize hematogenously to liver and lung. As in unilateral glucocorticoid-secreting adenomas, the surrounding adrenal cortex is atrophic.

3. **Bilateral nodular adrenal hyperplasia**—This can be due to ACTH stimulation (ACTH-dependent) or from several unique

ACTH-independent pathophysiologic disorders. Longstanding ACTH hypersecretion—either pituitary or nonpituitary—may result in nodular enlargement of the adrenal gland. The cortex between the nodules is not atrophic as there is ACTH stimulation to the entire gland. These focal nodules are often mistaken for adrenal neoplasms and may lead to unnecessary as well as unsuccessful unilateral adrenal surgery. In occasional cases these nodules may, over a period of time, even become autonomous or semiautonomous. Removal of the ACTH-secreting neoplasm results in regression of the adrenal nodules as well as resolution of hypercortisolism unless the nodules have already developed significant autonomy.

ACTH-independent bilateral nodular adrenal hyperplasia can be divided based on nodular size, diameter less than 1 cm (micronodular) or more than 1 cm (macronodular). Primary pigmented nodular adrenocortical disease (PPNAD) is a micronodular condition that has small to normal sized adrenal glands with multiple black and brown nodules with intranodular cortical atrophy. The pathology of nodules in bilateral macronodular adrenal hyperplasia (BMAH) is similar to unilateral disease, but the internodular cortex can be hyperplastic (commonly) or can be atrophic.

Pathogenesis and Genetics (Table 9–12)

A. Cushing disease The causes, natural history, and genetics of Cushing disease are reviewed in Chapter 4. Current evidence is consistent with the view that spontaneously arising corticotroph-cell pituitary adenomas are the primary cause and that the consequent ACTH hypersecretion and hypercortisolism lead to the characteristic endocrine abnormalities and hypothalamic dysfunction. This is supported by evidence showing that selective removal of these adenomas by pituitary microsurgery reverses the abnormalities and is followed by return of the HPA axis to normal. In addition, molecular studies have shown that nearly all corticotroph adenomas are monoclonal.

Although these primary pituitary adenomas are responsible for the great majority of cases, a few patients have been described in whom pituitary disease has been limited to corticotroph-cell

hyperplasia; these may be secondary to excessive CRH secretion by rare, benign hypothalamic gangliocytoma.

B. Ectopic ACTH syndrome and ectopic CRH syndrome
Ectopic ACTH syndrome arises when nonpituitary tumors synthesize and secrete biologically active ACTH. The related peptides β-lipotropin and β-endorphin are also synthesized and secreted, as are inactive ACTH fragments. Production of CRH has also been demonstrated in ectopic tumors secreting ACTH, but whether CRH plays a role in pathogenesis is unclear. A few cases in which nonpituitary tumors produced only CRH have been reported.

Ectopic ACTH syndrome occurs predominantly in selected tumor types (Figure 9–11); carcinoid tumors of lung, non-small cell, and small cell carcinoma of the lung account for most of the cases. Other tumors causing the syndrome are of neuroendocrine origin from cells in the thymus, gut, ovary, pancreatic islet, or thyroid (ie, C-cells). Multiple other tumor types have also been reported to cause the ectopic ACTH syndrome, but are very rare causes for it (see Chapter 21).

C. Nodular adrenal disease Recent discoveries have allowed a better understanding of the genetics responsible for nodular adrenal disease.

1. **Unilateral cortisol-secreting adrenal adenomas**—In 2013, four separate groups from around the world reported a mutation in the gene for the protein kinase A catalytic subunit, PRKACA. Together, these groups investigated more than 200 cortisol-secreting adrenal adenomas. They found mutations in the gene for PRKACA leading to constitutive activation of protein kinase A in more than 40% of the adenomas. The mutations were largely (95%) found in a single hotspot. These mutations were not found to surrounding normal adrenal tissue, in non-functional adenomas, adrenal cortical carcinomas, or in adrenal nodules with subtle cortisol hypersecretion (subclinical Cushing syndrome).

2. **Bilateral micronodular adrenal hyperplasia**—Primary pigmented nodular adrenocortical disease is an uncommon

TABLE 9–12 Genetic causes of adrenal dependent cushing syndrome.

Condition/Gene/Chromosome	Related Conditions	Nodular Disease
McCune Albright syndrome/GNAS1/20q13.3	Fibrous dysplasia of bone, café-au-lait skin pigmentation, precocious puberty	Unilateral or bilateral, micro- or macronodularity
Primary pigmented nodular adrenal disease/PRKAR1A/17q22-24	Carney Complex (myxomas, testicular tumors, thyroid nodules, growth hormone producing pituitary adenomas)	Bilateral, micronodular
Cortisol producing adenomas/PRKACA/19p13.1	No associated syndrome	Unilateral, usually macronodular
Familial adenomatous polyposis/APC/5q22.2	Multiple colon polyps and colon cancer	Unilateral or bilateral, macronodular
Multiple endocrine neoplasia type 1/MENIN/11q13	Primary hyperparathyroidism, pancreatic endocrine tumors, pituitary adenomas	Unilateral or bilateral, macronodular
Hereditary leiomyomatosis and renal cell cancer syndrome/fumarate hydratase/1q42.1	Hereditary leiomyomatosis, renal cell cancer, uterine fibroids	Bilateral, macromodular
Hereditary bilateral adrenal adenomas/ARMC5/16q11.2	Hereditary adrenal adenomas, often cortisol-producing (may be subclinical cortisol excess)	Bilateral, macronodular
FIGURE 9–11 Prevalence of the most common tumors causing ectopic ACTH secretion. (K, carcinoma; NET, neuroendocrine tumor; SCLC, small cell lung carcinoma). (Reproduced with permission from Isidori AM, Lenzi A. Ectopic ACTH syndrome. *Arq Bras Endocrinol Metabol*. 2007 Nov;51(8):1217-1225.)

familial cause of adrenal-dependent Cushing syndrome. It is associated with myxomas (cardiac, cutaneous, and mammary), spotty skin pigmentation, endocrine overactivity, sexual precocity, acromegaly, and schwannomas—referred to as the Carney complex. Germline inactivating mutations in the regulatory subunit of protein kinase A have been shown to cause constitutive activation of a pathway critical for cortisol production.

3. **Bilateral macronodular adrenal hyperplasia (BMAH)**—Multiple distinct entities exist that can result in BMAH. These adrenal nodules may be under the control of abnormal or ectopic hormone receptors. Aberrant regulation of cortisol production and adrenal growth has been shown in some of these patients to be mediated by the abnormal adrenal expression of receptors for a variety of hormones. The best characterized appears to be the expression of glucose-dependent insulinotropic polypeptide (GIP), whose adrenal expression has resulted in the modulation of cortisol production after physiologic postprandial fluctuation of endogenous levels of GIP, causing a state of *food-dependent Cushing syndrome*. Other abnormal hormone receptors that have been described in association with endogenous hypercortisolism with this phenomenon include vasopressin, beta-adrenergic agonists, human chorionic gonadotropin-LH, serotonin, angiotensin II, and leptin (see also Chapter 21). The identification of an ectopically expressed adrenal receptor raises the possibility of new pharmacologic approaches for control of hypercortisolism by suppressing the endogenous ligands or by blocking the abnormally expressed receptor with specific antagonists.

Another recent discovery that has furthered our knowledge of adrenal tumor genetics is that of the role of the armadillo-repeat containing 5 (ARMC5) gene. ARMC5 is a putative tumor suppressor gene located on chromosome 16p11.2. An investigation of apparently sporadic cases of BMAH showed mutations in both alleles of ARMC5, one germline and one somatic. The inactivating mutations in ARMC5 appear to

decrease steroidogenesis *in vitro* and may explain why very large nodules are required to produce cortisol excess. Several studies have looked at relatives of patients with BMAH and found germline mutations in over half of the studied relatives. In these individuals without any symptoms of Cushing syndrome, adrenal nodular hyperplasia was frequently discovered. It has also been reported that ACTH may be produced in the adrenal glands of patients with BMAH. This intraadrenal ACTH production may be the reason why there is internodular hyperplasia in many patients with BMAH.

McCune-Albright syndrome (characterized by fibrous dysplasia of bone, café-au-lait skin pigmentation, precocious puberty, and endocrine hormone excess) is caused by activating mutations of $G_s\alpha$ that lead to constitutive steroidogenesis in adrenal nodules carrying the mutation.

Additionally, BMAH has been found to be associated with several other genetic syndromes including multiple endocrine neoplasia type 1, familial adenomatous polyposis, and hereditary leiomyomatosis and renal cell cancer syndrome.

Pathophysiology (Figures 9–10 and 9–12)

A. Cushing disease   In Cushing disease, ACTH hypersecretion is random and episodic and causes cortisol hypersecretion in the absence of the normal circadian rhythm. Feedback inhibition of ACTH (secreted from the pituitary adenoma) by physiologic levels of glucocorticoids is suppressed; thus, ACTH hypersecretion persists despite elevated cortisol secretion and results in chronic glucocorticoid excess. The episodic secretion of ACTH and cortisol results in variable plasma levels that may at times be within the normal range. However, demonstration of elevated late-night serum or salivary cortisol levels, lack of suppression of cortisol after dexamethasone, or elevation of urine

Cushing syndrome suspected
(consider endocrinologist consultation)

Exclude exogenous glucocorticoid exposure

Perform one of the following tests

24-h UFC (≥2 tests)   Overnight   Late-night salivary
                             1-mg DST   cortisol (≥2 tests)

Consider caveats for each test (see text)
Use 48-h, 2-mg DST in certain populations (see text)

ANY ABNORMAL RESULT   Normal (CS unlikely)

Exclude physiologic causes of hypercortisolism (Table 9–2)

Consult endocrinologist

Perform 1 or 2 other studies shown above

Suggest consider or repeating the abnormal study
Suggest Dex-CRH or midnight serum cortisol in
certain populations (see text)

Cushing syndrome

FIGURE 9–12   The diagnosis of Cushing syndrome. (Reproduced with permission from Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing syndrome: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab.* 2008 May;93(5):1526-1540.)

free cortisol confirms cortisol hypersecretion (see sections on Laboratory Evaluation and Diagnosis of Cushing Syndrome). The overall increase in glucocorticoid secretion causes the clinical manifestations of Cushing syndrome. ACTH and **β-lipotropin** secretion are not usually elevated sufficiently to cause hyperpigmentation.

1. **Abnormalities of ACTH secretion**—Despite ACTH hypersecretion, stress responsiveness is absent; stimuli such as hypoglycemia or surgery fail to further elevate ACTH and cortisol secretion. This is probably due to suppression of hypothalamic function and CRH secretion by hypercortisolism, resulting in loss of hypothalamic control of ACTH secretion (see Chapter 4).
2. **Effect of cortisol excess**—Cortisol excess not only inhibits normal pituitary and hypothalamic function, affecting ACTH, TSH, GH, and gonadotropin release, but also results in all the systemic effects of glucocorticoid excess described in previous sections and in the section on Clinical Features later.
3. **Androgen excess**—Secretion of adrenal androgens is also increased in Cushing disease, and the degree of androgen excess parallels that of ACTH and cortisol. Thus, plasma levels of DHEA, DHEA sulfate, and androstenedione may be moderately elevated in Cushing disease; the peripheral conversion of

these hormones to testosterone and dihydrotestosterone leads to androgen excess. In women, this causes hirsutism, acne, and amenorrhea. In men with Cushing disease, cortisol suppression of LH secretion decreases testosterone secretion by the testis, resulting in decreased libido and impotence. The increased adrenal androgen secretion is insufficient to compensate for the decreased gonadal testosterone production.

B. Ectopic ACTH syndrome   Hypersecretion of ACTH and cortisol is usually greater in patients with ectopic ACTH syndrome than in those with Cushing disease. ACTH and cortisol hypersecretion is randomly episodic, and the levels are often greatly elevated. Usually, ACTH secretion by ectopic tumors is not subject to negative feedback control; that is, secretion of ACTH and cortisol is nonsuppressible with pharmacologic doses of glucocorticoids (see section on Diagnosis later).

Plasma levels, secretion rates, and urinary excretion of cortisol, the adrenal androgens, and DOC are often markedly elevated; despite this, the typical features of Cushing syndrome maybe absent, presumably because of rapid onset of hypercortisolism, anorexia, and other manifestations of the associated malignant disease. Features of mineralocorticoid excess (hypertension and

hypokalemia) are frequently present and have been attributed to increased secretion of DOC and the mineralocorticoid effects of cortisol. With ectopic CRH secretion, pituitary corticotroph hyperplasia and ACTH hypersecretion are observed along with resistance to negative feedback by cortisol.

C. Adrenal tumors

1. **Autonomous secretion**—Primary adrenal tumors, both adenomas and carcinomas, autonomously hypersecrete cortisol. Circulating plasma ACTH levels are suppressed, resulting in cortical atrophy of the uninvolved adrenal. Secretion is randomly episodic, and these tumors are typically unresponsive to manipulation of the hypothalamic-pituitary axis with pharmacologic agents such as dexamethasone and metyrapone.

2. **Adrenal adenomas**—Adrenal adenomas causing Cushing syndrome typically present solely with clinical manifestations of glucocorticoid excess, because they usually secrete only cortisol. Thus, the presence of androgen or mineralocorticoid excess should suggest that the tumor is an adrenocortical carcinoma.

3. **Adrenal carcinomas**—Adrenal carcinomas frequently hypersecrete multiple adrenocortical steroids and their precursors. Cortisol and androgens are the steroids most frequently secreted in excess; 11-deoxycortisol is often elevated, and there may be increased secretion of DOC, aldosterone, or estrogens. Plasma cortisol and urine free cortisol are often markedly increased; androgen excess is usually even greater than that of cortisol. Thus, high levels of plasma DHEA, DHEA sulfate, and of testosterone typically accompany the cortisol excess. Clinical manifestations of hypercortisolism are usually severe and rapidly progressive in these patients. In women, features of androgen excess are prominent; virilism may occasionally occur. Hypertension and hypokalemia are frequent and most commonly result from the mineralocorticoid effects of cortisol; less frequently, DOC and aldosterone hypersecretion also contribute.

Clinical Features (Table 9–13)

A. Symptoms and signs

1. **Obesity**—Obesity is the most common manifestation, and weight gain is usually the initial symptom. It is classically central, affecting mainly the face, neck, trunk, and abdomen, with relative sparing of the extremities. Generalized obesity with central accentuation is equally common, particularly in children.

   Accumulation of fat in the face leads to the typical facial rounding, *moon facies*, which is present in 75% of cases and is accompanied by facial plethora in most patients. Fat accumulation around the neck is prominent in the supraclavicular and dorsocervical fat pads.

   Obesity is absent in a handful of patients who do not gain weight; however, they usually have central redistribution of fat and a typical facial appearance.

2. **Skin changes**—Skin changes are frequent, and their presence should arouse a suspicion of cortisol excess. Atrophy of the epidermis and its underlying connective tissue leads to thinning (a transparent appearance of the skin) and facial plethora. Easy bruisability following minimal trauma is present in about 40%. Striae occur in 50% but are very unusual in patients over 40 years of age. These are typically red to purple, depressed below the skin surface secondary to loss of

TABLE 9–13 Clinical features of Cushing syndrome (% prevalence).

General
Obesity 90%
Hypertension 85%

Skin
Plethora 70%
Hirsutism 75%
Striae 50%
Acne 35%
Bruising 35%

Musculoskeletal
Osteopenia 80%
Weakness 65%

Neuropsychiatric 85%
Emotional lability
Euphoria
Depression
Psychosis

Gonadal Dysfunction
Menstrual disorders 70%
Impotence, decreased libido 85%

Metabolic
Glucose intolerance 75%
Diabetes 20%
Hyperlipidemia 70%
Polyuria 30%
Kidney stones 15%

underlying connective tissue, and wider (not infrequently >1-2 cm) than the pinkish-white striae that may occur with pregnancy or rapid weight gain. These striae are most commonly abdominal but may also occur over the breasts, hips, buttocks, thighs, and axillae.

Acne presenting as pustular or papular lesions may result from glucocorticoid excess or hyperandrogenism.

Minor wounds and abrasions may heal slowly, and surgical incisions sometimes undergo dehiscence.

Mucocutaneous fungal infections are frequent, including tinea versicolor, involvement of the nails (onychomycosis), and oral candidiasis.

Hyperpigmentation of the skin is rare in Cushing disease or adrenal tumors but is common in ectopic ACTH syndrome.

3. **Hirsutism**—Hirsutism is present in about 80% of female patients owing to hypersecretion of adrenal androgens. Facial hirsutism is most common, but increased hair growth may also occur over the abdomen, breasts, chest, and upper thighs. Acne and seborrhea usually accompany hirsutism. Virilism is unusual except in cases of adrenal carcinoma, in which it occurs in about 20% of patients.

4. **Hypertension**—Hypertension is a classic feature of spontaneous Cushing syndrome; it is present in about 75% of cases, and the diastolic blood pressure is greater than 100 mm Hg in over 50%. Hypertension and its complications contribute greatly to the morbidity and mortality rates in spontaneous Cushing syndrome.

5. **Gonadal dysfunction**—This is very common as a result of elevated androgens (in females) and cortisol (in males and to a lesser extent in females). Amenorrhea occurs in 75% of premenopausal women and is usually accompanied by

infertility. Decreased libido is frequent in males, and some have decreased body hair and soft testes.

6. **Central nervous system and psychologic disturbances—**Psychologic disturbances occur in the majority of patients. Mild symptoms consist of emotional lability and increased irritability. Anxiety, depression, poor concentration, and poor memory may also be present. Euphoria is frequent, and occasionally patients manifest overtly manic behavior. Sleep disorders are present in most patients, with either insomnia or early morning awakening.

   Severe psychologic disorders occur in a few patients and include severe depression, psychosis with delusions or hallucinations, and paranoia. Some patients have committed suicide. Loss of brain volume that is at least partially reversible following correction of hypercortisolism has been observed in several reports.

7. **Muscle weakness—**This occurs in about 60% of cases; it is more often proximal and is usually most prominent in the lower extremities. Hypercortisolism is associated with both low fat-free muscle mass and low total body protein.

8. **Osteoporosis—**Owing to the profound effects of glucocorticoids on the skeleton, patients with Cushing syndrome frequently have evidence of significant osteopenia and osteoporosis. Patients may present with multiple fragility fractures—typically of the feet, ribs, or vertebrae. Back pain may be the initial complaint. Compression fractures of the spine are demonstrated radiographically in 15% to 20% of patients. In fact, unexplained osteopenia in any young or middle-aged adult should always prompt an evaluation for Cushing syndrome, even in the absence of any other signs or symptoms of cortisol excess. Although avascular necrosis of bone has been associated with exogenous glucocorticoid administration, the problem is rarely observed in patients with endogenous hypercortisolism.

9. **Renal calculi—**Calculi secondary to glucocorticoid-induced hypercalciuria occur in approximately 15% of patients, and renal colic may occasionally be a presenting complaint.

10. **Thirst and polyuria—**Polyuria is rarely due to overt hyperglycemia but is usually caused by glucocorticoid-induced inhibition of vasopressin (antidiuretic hormone or ADH) secretion and the direct enhancement of renal free water clearance by cortisol.

11. **Growth deceleration—**In children, nearly all (>95%) show decreasing linear growth. Weight gain accompanying decreasing linear growth in a child should prompt an evaluation for Cushing syndrome.

B. Laboratory findings   Routine laboratory examinations are described here. Specific tests to establish the diagnosis of Cushing syndrome are discussed in the section on Diagnosis.

High normal hemoglobin, hematocrit, and red cell counts are usual; polycythemia is rare. The total white count is usually normal; however, both the percentage of lymphocytes and the total lymphocyte count may be subnormal. Eosinophils are also depressed, and a total eosinophil count less than $100/\mu L$ is present in most patients. Serum electrolytes, with rare exceptions, are normal in Cushing disease; however, hypokalemic alkalosis occurs when there is marked steroid hypersecretion with the ectopic ACTH syndrome or adrenocortical carcinoma.

Although fasting hyperglycemia occurs in only 10% to 15% of patients, glucose intolerance is a relatively common finding and occurs in 60% of patients. Most patients have secondary hyperinsulinemia and abnormal glucose tolerance tests.

Serum calcium is normal; serum phosphorus is low normal or slightly depressed. Hypercalciuria is present in 40% of cases.

C. Imaging studies   Routine radiographs may reveal cardiomegaly, due to hypertensive or atherosclerotic heart disease, or mediastinal widening, due to central fat accumulation. Vertebral compression fractures, rib fractures, and renal calculi may be present.

D. Electrocardiographic findings   Hypertensive, ischemic, and electrolyte-induced changes may be present on the electrocardiogram.

Features Suggesting a Specific Cause

A. Cushing disease   Cushing disease typifies the classic clinical picture: female predominance, onset generally between ages 20 and 40, and a slow progression over several years. Hyperpigmentation and hypokalemic alkalosis are rare; androgenic manifestations are limited to acne and hirsutism. In general, secretion of cortisol and adrenal androgens is only moderately increased.

B. Ectopic ACTH syndrome (carcinoma)   In contrast, this syndrome occurs predominantly in males, with the highest incidence between ages 40 and 60. The clinical manifestations of hypercortisolism are frequently limited to weakness, hypertension, and glucose intolerance; the primary tumor is usually apparent. Hyperpigmentation, hypokalemia, and alkalosis are common, as are weight loss and anemia. The hypercortisolism is of rapid onset, and steroid hypersecretion is frequently severe, with equally elevated levels of glucocorticoids, androgens, and DOC.

C. Ectopic ACTH syndrome (benign tumor)   A minority of patients with ectopic ACTH syndrome due to more benign tumors, especially bronchial carcinoids, present a more slowly progressive course, with typical features of Cushing syndrome. These patients may be clinically identical to those with pituitary-dependent Cushing disease, and the responsible tumor may not be apparent. Hyperpigmentation, hypokalemic alkalosis, and anemia are variably present. Further confusion may arise, since a number of these patients with occult ectopic tumors may have ACTH and steroid dynamics typical of Cushing disease (see later).

D. Adrenal adenomas   The clinical picture in patients with adrenal adenomas is usually that of glucocorticoid excess alone, and androgenic effects such as hirsutism are absent. Onset is gradual, and hypercortisolism is mild to moderate. Plasma androgens are usually in the low normal or subnormal range.

E. Adrenal carcinomas   In general, adrenal carcinomas have a rapid onset of the clinical features of excessive glucocorticoid, androgen, and mineralocorticoid secretion and are rapidly progressive. Marked elevations of both cortisol and androgens are usual; hypokalemia is common, as are abdominal pain, palpable masses, and hepatic and pulmonary metastases.

Diagnosis

The clinical suspicion of Cushing syndrome must be confirmed with biochemical studies. Initially, a general assessment of the patient regarding the presence of other illnesses, drugs, alcohol, or psychiatric problems must be done since these factors may confound the evaluation. In the majority of cases, the biochemical diagnosis of Cushing syndrome can be easily performed in the ambulatory setting (see Figure 9–12).

A. Dexamethasone suppression test   The overnight 1-mg dexamethasone suppression test is a valuable screening test in patients with suspected hypercortisolism. This study employs the administration of 1 mg of dexamethasone at bedtime (11:00 PM), with determination of a plasma cortisol early the following morning. Normal subjects should suppress plasma cortisol to less than 1.8 μg/dL (50 nmol/L) following an overnight 1-mg test. Although a level of less than 5 μg/dL has been used in the past, several false-negative studies have been discovered using this test criterion. False-negative results may occur in some patients with mild hypercortisolism and in those with intermittent hypercortisolism. False-positive results with the overnight 1-mg dexamethasone suppression test may be caused by drugs that accelerate dexamethasone metabolism (phenytoin, phenobarbital, rifampin) or by drugs that increase CBG and resultant total cortisol levels (estrogens). False-positive results also occur in patients with renal failure, depression, alcoholism, or in patients undergoing a stressful event or serious illness.

B. Urine free cortisol   Another study used in the diagnosis of Cushing syndrome is the determination of urine free cortisol measured by HPLC or LC/MS/MS in a 24-hour urine collection. These methods are highly accurate and specific for the measurement of cortisol. Commonly used drugs and medications do not interfere; however, carbamazepine and fenofibrate can cause falsely elevated results with HPLC since they elute with cortisol. Urinary free cortisol is usually less than 50 μg/24 h (<135 nmol/24 h) when measured by HPLC or LC/MS/MS. The major liability of urine free cortisol is its poor sensitivity for detecting patients with mild to moderate hypercortisolism (sensitivity <75%). Consequently, this modality should not be used alone to exclude Cushing syndrome.

C. Late-night serum and salivary cortisol   The absence of diurnal cortisol rhythm is a hallmark of Cushing syndrome. Normally, cortisol is secreted episodically with a diurnal rhythm paralleling the secretion of ACTH. Levels are usually highest early in the morning and decrease gradually throughout the day, reaching the nadir in the late evening between 11:00 PM and midnight. Several studies have demonstrated that an elevated midnight plasma cortisol level (>5.2-7.0 μg/dL [140-190 nmol/L]) is highly accurate in differentiating patients with Cushing syndrome from normal subjects and from patients with pseudo-Cushing conditions such as depression or alcoholism.

Because obtaining such plasma cortisol measurements is impractical on an ambulatory basis, the measurement of salivary cortisol provides a simple and more convenient means of probing nighttime cortisol secretion. Saliva can easily be sampled at home by the patient using a variety of techniques. Reference ranges for late-night salivary cortisol concentrations are dependent on the assay employed; however, using a radioimmunoassay, normal subjects should have values less than 0.15 μg/dL (4 nmol/L).

Problems in Diagnosis

It has become increasingly appreciated that many common physiologic situations and medical disorders can also cause sustained or intermittent hypercortisolism and may mimic—clinically and biochemically—the neoplastic causes of Cushing syndrome with which we are so familiar (pituitary/nonpituitary ACTH-secreting tumors and adrenal neoplasia). These disorders have been characterized as "pseudo-Cushing syndrome." Of course, the clinical features of Cushing syndrome such as obesity, hypertension, diabetes, myopathy, osteoporosis, and neuropsychiatric problems may be evident in some patients with chronic physiologic/nonneoplastic hypercortisolism (eg, depression, chronic alcoholism, and chronic kidney disease) and be indistinguishable from those with pathologic Cushing syndrome.

These conditions may have biochemical features of Cushing syndrome, including elevations of urine free cortisol, disruptions in the normal diurnal pattern of cortisol secretion, and lack of suppression of cortisol after the overnight 1-mg dexamethasone suppression test. Although the history and physical examination may provide specific clues to the appropriate diagnosis, definitive biochemical confirmation may be difficult and may require repeated testing.

The ACTH and cortisol responses to DDAVP have been used to distinguish patients with pathologic/neoplastic Cushing syndrome from those with physiologic/non-neoplastic hypercortisolism. Since corticotroph adenomas harbor vasopressin receptors, patients with Cushing disease have an exaggerated ACTH response to desmopressin (peak response >70 pg/mL [>15.4 pmol/L] or an increase >27 pg/mL [>5.9 pmol/L]), while those with alcohol-induced Cushing syndrome (and other nonneoplastic hypercortisolemic states) have a blunted ACTH response. The cortisol responses have been less valuable in this differentiation.

Another study to distinguish mild Cushing syndrome from pseudo-Cushing conditions is the use of dexamethasone suppression followed by CRH stimulation. This test takes advantage of differential response of patients with Cushing syndrome and pseudo-Cushing syndrome to both dexamethasone and CRH by combining these tests to provide greater accuracy in the diagnosis. This study involves the administration of dexamethasone, 0.5 mg every 6 hours for eight doses, followed immediately by a CRH stimulation test, starting 2 hours after the completion

of the low-dose dexamethasone suppression. A plasma cortisol concentration greater than 1.4 μg/dL (38.6 nmol/L) measured 15 minutes after administration of CRH correctly identifies the majority of patients with Cushing syndrome. After administration of high-dose dexamethasone, patients with pseudo-Cushing syndrome do not have a rise in cortisol or ACTH in response to CRH. However, it is now appreciated that some patients with pseudo-Cushing syndrome (eg, anorexia nervosa) may have abnormal dexamethasone-CRH suppression tests.

Differential Diagnosis

The differential diagnosis of Cushing syndrome can be difficult and should always be performed in consultation with an endocrinologist. The introduction of several technologic advances, including a specific and sensitive IRMA or ICMA for ACTH, CRH stimulation test, inferior petrosal sinus sampling (IPSS), CT and magnetic resonance imaging (MRI) of the pituitary and adrenal glands have all provided means for an accurate differential diagnosis.

A. Plasma ACTH Initially, the differential diagnosis for Cushing syndrome must distinguish between ACTH-dependent Cushing syndrome (pituitary or nonpituitary ACTH-secreting neoplasm) and ACTH-independent hypercortisolism. The best way to distinguish these forms of Cushing syndrome is measurement of plasma ACTH by IRMA or ICMA. The development of this sensitive and specific test has made it possible to reliably identify patients with ACTH-independent Cushing syndrome. The ACTH level is generally less than 10 pg/mL (2.2 pmol/L) and exhibits a blunted response to CRH (peak response

<10 pg/mL [2.2 pmol/L]) in patients with cortisol-producing adrenal neoplasms, autonomous bilateral adrenal cortical hyperplasia, and factitious Cushing syndrome (Figure 9–13). Patients with ACTH-secreting neoplasms usually have plasma ACTH levels greater than 20 pg/mL (4.4 pmol/L) and frequently greater than 52 pg/mL (11.5 pmol/L). The major challenge in the differential diagnosis of ACTH-dependent Cushing syndrome is identifying the source of the ACTH-secreting tumor. The vast majority of these patients (90%) have a pituitary tumor, whereas the others harbor a nonpituitary neoplasm. Diagnostic studies needed to differentiate these two entities must yield nearly perfect sensitivity, specificity, and accuracy. Although plasma ACTH levels are usually higher in patients with ectopic ACTH than those with pituitary ACTH-dependent Cushing syndrome, there is considerable overlap between these two entities. Many of the ectopic ACTH-secreting tumors are radiologically occult at the time of presentation and may not become clinically apparent for many years after the initial diagnosis. However, an enhanced ACTH response for CRH administration is more frequently found in pituitary Cushing syndrome compared with ectopic ACTH syndrome.

B. Pituitary MRI When ACTH-dependent Cushing syndrome is present, MRI of the pituitary gland with gadolinium enhancement should be performed and will identify an adenoma in at least 50% to 60% of the patients. If the patient has classic clinical laboratory findings of ACTH-dependent hypercortisolemia and an unequivocal pituitary lesion on MRI, the likelihood of Cushing disease is 98% to 99%. However, it must be emphasized that approximately 10% of the population in the age group from 20 to 50 years will have incidental tumors of the

ACTH-IRMA measurements in pituitary-adrenal disorders
FIGURE 9–13 Plasma ACTH-IRMA (pmol/L or pg/mL) of patients with pituitary-adrenal disorders. Dashed horizontal lines indicate reference range. CD = Cushing disease, EAS = Ectopic ACTH syndrome, ACS = Adrenal ACTH-independent Cushing syndrome, 1⁰ AI = primary adrenal insufficiency, 2⁰ AI = Secondary adrenal insufficiency, Pit = Secondary adrenal insufficiency due to pituitary disease, Steroids = Secondary adrenal insufficiency due to exogenous steroid use.

pituitary demonstrable by MRI. Therefore, some patients with ectopic ACTH syndrome will have radiographic evidence of a pituitary lesion.

C. High-Dose dexamethasone suppression   Traditionally, the high-dose dexamethasone suppression test has been utilized in the differential diagnosis of Cushing syndrome. However, the diagnostic accuracy of this procedure is only 70% to 80%, which is actually less than the pretest probability of Cushing disease—on average about 90%. As a result, this study is no longer recommended.

D. Inferior petrosal sinus sampling (IPSS)   The most definitive means of accurately distinguishing pituitary from nonpituitary ACTH-dependent Cushing syndrome is the use of bilateral simultaneous IPSS with CRH stimulation, and this procedure is the next step in the evaluation of patients with ACTH-dependent Cushing syndrome when MRI does not reveal a definite adenoma. This study takes advantage of the means by which pituitary hormones reach the systemic circulation. Blood leaves the anterior lobe of the pituitary and drains into the cavernous sinuses, which then empty into the inferior petrosal sinuses and subsequently into the jugular bulb and vein. Simultaneous inferior petrosal sinus and peripheral ACTH measurement before and after CRH stimulation can reliably confirm the presence or absence of an ACTH-secreting pituitary tumor. An inferior petrosal sinus to peripheral (IPS-P) ACTH ratio greater than 2.0 prior to CRH and greater than 3.0 after CRH is consistent with a pituitary ACTH-secreting tumor, and an IPSP ACTH ratio less than 1.8 supports the diagnosis of ectopic ACTH. Anatomical variants can cause false-negative studies; however, simultaneous measurement of PRL can be used to construct a PRL-normalized ACTH ratio that can eliminate false negatives caused by anatomical variants.

Bilateral IPSS with CRH stimulation does require a skilled interventional radiologist. However, in experienced hands, the procedure has yielded a diagnostic accuracy approaching 100% in identifying the source of ACTH-dependent Cushing syndrome.

E. Occult ectopic ACTH   If the IPSS study is consistent with a nonpituitary ACTH-secreting tumor, a search for an occult ectopic ACTH-secreting tumor is needed. Because the majority of these lesions are in the thorax, high-resolution CT of the chest may be useful; MRI of the chest may have even better sensitivity in finding these lesions, which are usually small bronchial carcinoid tumors. Unfortunately, utilization of a radiolabeled somatostatin analog scan (octreotide acetate scintigraphy) has met with only mixed results in localizing these tumors.

F. Adrenal localizing procedures   CT (Figure 9–14) and MRI are used to define adrenal lesions. Their primary use is to localize adrenal tumors in patients with ACTH-independent Cushing syndrome. Most adenomas exceed 2 cm in diameter
FIGURE 9–14   Adrenal CT scan in Cushing syndrome. The patient has family history of macronodular adrenal disease with associated Cushing syndrome. Both adrenal glands visualized in this CT have nodular enlargement with the right adrenal gland showing significant macronodular hyperplasia. The adrenal nodules seen here have low CT attenuation, indicative of non-malignant lesions.

and have a low density on CT; carcinomas are usually much larger with irregular borders and have high density and low contrast washout on CT.

TREATMENT

A. Cushing disease   The aim of treatment of Cushing syndrome is to remove or destroy the causative lesion and thus correct hypersecretion of adrenal hormones without inducing pituitary or adrenal damage, which requires permanent replacement therapy for hormone deficiencies.

The treatment of choice for Cushing disease is transsphenoidal pituitary microsurgery with adenomectomy. Complete removal of the ACTH-secreting pituitary lesion resolves ACTH hypersecretion and generally induces transient adrenal insufficiency. This is due to suppression of normal pituitary corticotrophs from cortisol excess. In most cases, the adrenal insufficiency resolves within several months, and normal cortisol dynamics are restored. If complete resection of the causative lesion is not possible, radiation therapy to the pituitary lesion or medical therapy to lower cortisol levels can be implemented. In some cases bilateral adrenalectomy is needed to control the hypercortisolism. These methods are discussed in greater detail in Chapter 4.

B. Ectopic ACTH syndrome   Cure of ectopic ACTH syndrome is usually possible only in cases involving the more benign tumors such as bronchial or thymic carcinoids or pheochromocytomas. Treatment is made difficult by the presence of metastatic tumors and accompanying severe hypercortisolism. If therapy directed to the primary tumor is unsuccessful, other means (such as bilateral adrenalectomy, glucocorticoid inhibitors, or glucocorticoid receptor antagonists) must be used to correct the steroid-excess state.

Severe hypokalemia may require potassium replacement in large doses and spironolactone to block mineralocorticoid effects.

C. Adrenal tumors

1. **Adrenal adenomas**—Patients with adrenal adenomas are successfully treated by unilateral adrenalectomy, and the outlook is excellent. Laparoscopic adrenalectomy has become widely used in most patients with benign adrenal tumors and has significantly reduced the duration of the hospital stay. Because the hypothalamic-pituitary axis and the contralateral adrenal are suppressed by prolonged cortisol secretion, these patients often have postoperative adrenal insufficiency and require glucocorticoid therapy both during and following surgery until the remaining adrenal recovers.
2. **Adrenal carcinomas**—Therapy in cases of adrenocortical carcinoma is less satisfactory, because the tumor has frequently already metastasized (usually to the retroperitoneum, liver, and lungs) by the time the diagnosis is made.
   a. **Operative treatment**—Surgical cure depends on the size and extent of the tumor, and cure is not possible in metastatic or locally advanced disease. Persisting nonsuppressible steroid secretion in the immediate postoperative period indicates residual or metastatic tumor.
   b. **Medical treatment**—Mitotane is the drug of choice. The dosage is 6 to 12 g/d orally in three or four divided doses. The dose must be reduced because of side-effects in 80% of patients (diarrhea, nausea and vomiting, depression, somnolence). About 70% of patients achieve a reduction of steroid secretion, but only 35% achieve a reduction in tumor size.

Ketoconazole and metyrapone (singly or in combination) are useful in controlling steroid hypersecretion in patients who do not respond to mitotane.

D. Bilateral macrodular adrenal hyperplasia

Bilateral adrenalectomy is curative in these patients, but the decision to perform bilateral adrenalectomy must be weighed against the resultant adrenal insufficiency and its inherent morbidity. Some evidence exists that unilateral adrenalectomy of the largest adrenal gland can provide control of the hypercortisolism for at least some time before removal of the other adrenal gland is needed.

PROGNOSIS

A. Cushing syndrome
Untreated Cushing syndrome is frequently fatal, and death may be due to the underlying tumor itself, as in the ectopic ACTH syndrome and adrenal carcinoma. However, in most cases, death is the consequence of sustained hypercortisolism and its complications, including hypertension, cardiovascular disease, stroke, thromboembolism, and susceptibility to infection.

B. Cushing disease
In contrast to patients with untreated Cushing syndrome, individuals with Cushing disease who achieve normalization of cortisol levels as result of therapy have a standard mortality ratio (SMR) similar to age-matched populations. However, patients with persistent hypercortisolism despite treatment continue to have an increased SMR (3.8- to 5.0-fold), when compared to the general population.

With current pituitary microsurgery, the majority of patients with Cushing disease can be treated successfully with remission rates of 65% to 90% in patients with tumors less than 1 cm and approximately 65% in patients with tumors more than 1 cm. Even with initial remission, up to 25% of patients with small tumors may have recurrence at 5 to 10 years after therapy. Unfortunately, reduction in health-related quality of life, especially related to psychological functioning, and metabolic derangements may persist after successful surgery.

C. Adrenal tumors
The prognosis in adrenal adenomas is excellent. In adrenal carcinoma, the prognosis is almost universally poor, and the median survival from the date of onset of symptoms is about 4 years.

D. Ectopic ACTH syndrome
Prognosis is also poor in patients with ectopic ACTH syndrome due to the nature of the malignancy producing the hormone, and in these patients with severe hypercortisolism, survival is frequently only days to weeks. Some patients respond to tumor resection or chemotherapy. The prognosis is better in patients with benign tumors producing the ectopic ACTH syndrome.

HIRSUTISM AND VIRILISM

Excessive adrenal or ovarian secretion of androgens or excessive conversion of weak androgens to testosterone and dihydrotestosterone in peripheral tissues leads to hirsutism and virilism (see Chapter 13). As previously discussed, the adrenal secretory products DHEA, DHEA sulfate, and androstenedione are weak androgens; however, the peripheral conversion to testosterone and dihydrotestosterone can result in a state of androgen excess.

Excessive androgen production is seen in both adrenal and ovarian disorders. Adrenal causes include Cushing syndrome, adrenal carcinoma, and congenital adrenal hyperplasia (see previous sections and Chapter 14). Mild adult-onset cases of congenital adrenal enzyme deficiencies have been described; these appear to be relatively uncommon. Biochemical diagnosis of late-onset 21-hydroxylase deficiency is best achieved by measurement of the 17-hydroxyprogesterone response to ACTH. Ovarian causes are discussed in Chapter 13.

In children, androgen excess is usually due to premature adrenarche, congenital adrenal hyperplasia, or adrenal carcinoma. In women, hirsutism accompanied by amenorrhea, infertility, and ovarian enlargement is typical of the polycystic ovary syndrome, whereas in Cushing syndrome hirsutism is accompanied by features of cortisol excess. Late-onset 21-hydroxylase deficiency is accompanied by elevated levels of plasma 17-hydroxyprogesterone, especially following ACTH administration. Virilism and severe androgen excess in adults are usually due to androgen-secreting adrenal or ovarian tumors; virilism is unusual in the polycystic ovary syndrome and rare in Cushing disease. In the absence of these syndromes, hirsutism in women

is usually idiopathic or due to milder forms of polycystic ovary syndrome. Exogenous androgen administration (eg, DHEA) should also be considered.

The diagnosis and therapy of hirsutism are discussed in Chapter 13.

INCIDENTAL ADRENAL MASS

The incidental adrenal mass has become a common diagnostic problem, because approximately 2% to 4% of patients undergoing CT studies of the abdomen are found to have focal enlargement of the adrenal gland. Adrenal masses in an adult may represent functional or nonfunctional cortical adenomas or carcinoma, pheochromocytomas, cysts, myelolipomas, or metastasis from other tumors. Congenital adrenal hyperplasia may also uncommonly present as a focal enlargement of the adrenal gland, and adrenal hemorrhage also causes enlargement.

Investigation of an incidental adrenal mass should focus on two distinct areas: (1) exclusion of malignancy; and (2) exclusion of hormonal excess.

Exclusion of Malignancy

When trying to determine if an adrenal mass is malignant, lesion size and appearance are helpful features, as most adrenal carcinomas and metastatic lesions are large (>4 cm) and have irregular or invasive borders. The most definitive features used to exclude malignancy are CT density and contrast washout. Lesions with low density (<10 Hounsfield units) on unenhanced CT scans are almost certainly benign, but some benign lesions have a density more than 10 Hounsfield units. In cases where the lesion does not have a low density, administration of contrast with delayed imaging is very helpful. Benign lesions have a contrast washout of more than 50%, whereas malignant lesions have a low amount of contrast washout.

MRI of the adrenal gland is usually not necessary but may be helpful in selected patients. Typically, malignancies and pheochromocytomas tend to have bright signal intensity with T2-weighted images. Percutaneous adrenal biopsy really has no demonstrated efficacy in patients with adrenal masses and no history of a malignancy. Percutaneous adrenal biopsy should be reserved for patients in whom the presence or absence of adrenal metastases may alter the therapy or prognosis of the patient. Pheochromocytoma should always be excluded before biopsy is undertaken.

Endocrine Evaluation

The appropriate biochemical evaluation of an incidental adrenal mass should include testing for pheochromocytoma, cortisol excess, and in patients with hypertension or hypokalemia, primary aldosteronism. To exclude pheochromocytoma, all patients with incidental adrenal masses should have a measurement of fractionated urinary or plasma metanephrines. Cortisol excess should also be evaluated in all patients. It appears that the overnight (1-mg) dexamethasone suppression test is the most sensitive test for cortisol excess in patients with mild adrenal-dependent cortisol excess.

A serum potassium and plasma aldosterone concentration-PRA ratio should be determined to evaluate for primary aldosteronism in individuals with hypertension or hypokalemia.

Repeat CT imaging in 6 to 12 months is also recommended in most cases. Demonstrating a lack of growth in a mass helps to further exclude neoplastic disease. Hormonal abnormalities may develop over time in nodules that were previously non-secretory, and follow-up testing has been recommended by some, depending on the clinical context.

Cortisol-Producing Adenoma

The most common functioning lesion in patients with an incidentally discovered adrenal mass appears to be an adenoma with autonomous secretion of cortisol. Traditional significant cortisol excess occurs in 6% to 9% of patients with incidental adrenal masses. Lesions with autonomous cortisol hypersecretion generally range in size from 2 to 5 cm in diameter. It is now well recognized that adrenal adenomas may secrete small but excessive amounts of cortisol. Although these lesions do not cause typical Cushing syndrome features, over time, the low level of cortisol excess is sufficient to contribute to low bone density, metabolic syndrome, and hypertension. Patients with prolonged, excessive low levels of autonomous cortisol secretion have been described as having mild cortisol excess or *subclinical* Cushing syndrome. The complete natural history of this autonomous cortisol secretion is unknown, but recent studies have shown an increase in cardiovascular morbidity and mortality in these patients. Studies have shown that surgical removal of adrenal adenomas in patients with even mild cortisol excess may result in improvement in their metabolic profile (ie, hypertension, obesity, diabetes) and a reduction in the incidence of future vertebral compression fractures. Consequently, adrenalectomy should be considered in patients with subclinical Cushing syndrome, especially in patients with clinical problems that might potentially be aggravated by glucocorticoid excess.

These patients are best identified by their failure to suppress cortisol to less than 1.8 μg/dL (50 nmol/L) following an overnight 1-mg dexamethasone suppression test. In addition, the basal levels of ACTH in these patients are subnormal or frankly suppressed. DHEA sulfate levels are also usually decreased in patients with cortisol-secreting adenomas, likely reflecting ACTH suppression. The autonomous cortisol secretion by the tumor may result in blunting of diurnal variation and in some cases, but not all, elevation of urine free cortisol levels. The low plasma ACTH level manifests in a blunted response to CRH administration. Removal of these silent adrenocortical adenomas may be followed by clinically significant secondary adrenal insufficiency.

Pheochromocytoma

Pheochromocytoma is a potentially life-threatening tumor that may present as an incidental adrenal mass. Surprisingly, pheochromocytoma may account for as many as 2% to 3% of incidental adrenal lesions. Many of these patients have hypertension and symptoms associated with catecholamine excess such as headache, diaphoresis, palpitations, or nervousness (see Chapter 11).

Aldosterone-Producing Adenoma

Although aldosterone-producing adenomas are more common than either pheochromocytomas or cortisol-producing adenomas, they actually represent a very unusual cause of an incidentally discovered adrenal mass. This appears to be due to the fact that aldosterone-producing adenomas are usually small and frequently missed with CT imaging of the adrenal gland. Because most of these patients have hypertension, this diagnosis needs to be considered only in patients with hypertension. The presence of hypokalemia should arouse suspicion of this diagnosis, but hypokalemia is not invariably present. It is usually present in patients with aldosterone-producing adenomas greater than 3 cm. Hyperaldosteronism can be excluded by the measurement of aldosterone and PRA. If the aldosterone (ng/dL)-PRA (ng/mL/h) ratio is less than 20 to 30 and plasma aldosterone is less than 14 ng/dL, an aldosterone-producing adenoma is excluded.

GLUCOCORTICOID THERAPY FOR NONENDOCRINE DISORDERS

Principles

Glucocorticoids have been used for their anti-inflammatory and immunosuppressive activity in treatment of a wide variety of disorders. These include rheumatologic disorders (eg, rheumatoid arthritis and systemic lupus erythematosus), pulmonary diseases (eg, asthma), renal disease (eg, glomerulonephritis), and many others. Because of their side-effects, glucocorticoids should be used in the minimum effective dose and for the shortest possible duration of therapy.

Synthetic Glucocorticoids

Steroid compounds have been synthesized, taking advantage of chemical alterations to the steroid nucleus that enhances glucocorticoid activity relative to mineralocorticoid activity. For example, prednisone has a double bond between positions 1 and 2 of cortisol and an 11-keto group instead of a hydroxyl group. It has three to five times more glucocorticoid activity than cortisol and relatively little mineralocorticoid activity. It must be converted to prednisolone by reduction of the 11-keto group to a hydroxyl group in order to be biologically active, a process that may be reduced in the presence of liver disease. Dexamethasone has the same additional double bond, a fluoro atom in the 9α position and a 16α-methyl group. This results in 10 to 20 times the glucocorticoid activity of cortisol and negligible mineralocorticoid activity. Many other compounds have been synthesized. Although most synthetic glucocorticoids exhibit little binding to CBG, their plasma half-lives are longer than that of cortisol.

Modes of Administration

Glucocorticoids may be administered parenterally, orally, topically, and by inhalation. Absorption rates from intramuscular and intra-articular sites depend on the particular glucocorticoid and its formulation. Transdermal absorption also depends on the severity of the inflammatory disorder, the area of the body to which the drug is applied, the presence of vehicles that enhance absorption (eg, urea), and the use of an occlusive dressing. Inhaled glucocorticoids vary in their bioavailability; the technique of administration (eg, use of spacers) also affects the amount of drug delivered to the lungs.

Side-Effects

In general, the severity of the side-effects is a function of dose and duration of therapy, but there is marked individual variation.

A. Hypothalamic-pituitary-adrenal axis suppression Glucocorticoids suppress CRH and ACTH secretion (negative feedback). Suppression of the HPA axis may occur at any dose of glucocorticoid, but generally with doses of prednisone greater than 5 mg/d. It is difficult, however, to predict the development or degree of suppression in any given individual. In general, patients who develop clinical features of Cushing syndrome or who have received glucocorticoids equivalent to 10 to 20 mg of prednisone per day for 3 weeks or more should be assumed to have clinically significant HPA axis suppression. Patients treated with alternate-day steroid regimens exhibit less suppression than those who receive steroids daily.

B. Cushing syndrome Glucocorticoid administration results in the development of Cushingoid features. Of special concern is steroid-induced osteoporosis, particularly in patients for whom a long course of steroid therapy is anticipated. The severity of systemic effects of inhaled glucocorticoids varies among different preparations. However, they are associated with both local effects (dysphonia and oral candidiasis) and systemic effects, especially glaucoma, cataracts, osteoporosis, and growth retardation in children. Protease inhibitors are now well recognized to decrease the metabolism of exogenous glucocorticoids. When the two are used in combination, the resultant increase in circulating glucocorticoid can lead to exogenous Cushing syndrome.

C. Steroid withdrawal Because of their adverse effects, glucocorticoids must be tapered downward as the clinical situation permits. Tapering regimens are essentially empirical. Factors that may limit the ability to taper the dose down to physiologic replacement levels include recrudescence of disease and steroid withdrawal syndrome. The latter appears in a variety of patterns. Patients may develop fatigue, arthralgias, and desquamation of the skin. Psychologic dependence has also been described. Even after the dose has been reduced to physiologic levels, HPA axis suppression (ie, secondary adrenal insufficiency) persists for an average of 9 to 10 months but may continue for as long as 1 to 2 years.

Hypertension affects one in four adults in the developed world. Although hypertension is *essential* or *idiopathic* in most cases, a cause can be detected in approximately 15% of the hypertensive population. The secondary causes of hypertension can be divided into renal (eg, renal vascular or parenchymal disease) and endocrine causes. There are at least 14 endocrine disorders in which hypertension may be the initial clinical presentation (Table 10–1). The diagnosis of endocrine hypertension presents the clinician an opportunity to provide a surgical cure or to achieve a marked response with targeted pharmacologic therapy. Pheochromocytoma and Cushing syndrome are reviewed in detail in Chapters 11 and 9, respectively. The renin-angiotensin-aldosterone system, the diagnostic and therapeutic approaches to mineralocorticoid hypertension (eg, primary aldosteronism), and less common forms of endocrine hypertension are reviewed in this chapter.

RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

The components of the renin-angiotensin-aldosterone system are shown in Figure 10–1. Aldosterone is secreted from the zona glomerulosa under the primary control of angiotensin II, potassium, and corticotropin (ACTH). The secretion of aldosterone is restricted to the zona glomerulosa because of zonal-specific expression of aldosterone synthase (CYP11B2). Hypokalemia, atrial natriuretic peptide (ANP), dopamine, and heparin inhibit aldosterone secretion.

Renin and Angiotensin

Renin is an enzyme produced in the juxtaglomerular apparatus of the kidney, stored in granules, and released in response to specific secretagogues. The first 43 amino acids of the 340 amino acid renin protein are a prosegment cleaved to produce the active enzyme. The release of renin into the circulation is the rate-limiting step in the activation of the renin-angiotensin-aldosterone system. Renal renin release is controlled by: juxtaglomerular cells acting as pressure transducers that sense stretch of the afferent arteriolar wall and thus renal perfusion pressure; the macula densa, a specialized group of convoluted distal tubular cells that function as chemoreceptors for monitoring the sodium and chloride loads present in the distal tubule; and, the sympathetic nervous system, which modifies the release of renin, particularly in response to upright posture; and humoral factors, including potassium, angiotensin II, and ANPs. Thus, renin release is maximized in conditions of low renal perfusion pressure or low tubular sodium content (eg, renal artery stenosis, hemorrhage, dehydration). Renin release is suppressed by elevated perfusion pressure at the kidney (eg, hypertension) and high sodium diets.

FIGURE 10–2 Steps in the production of angiotensin peptides by the renin-angiotensin system (ACE, angiotensin-converting enzyme).

Renin release is increased directly by hypokalemia and decreased by hyperkalemia.

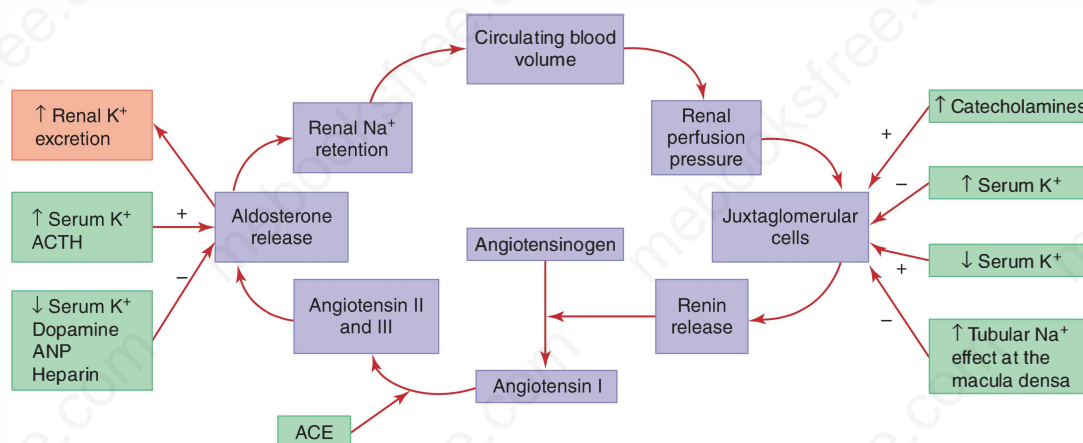
Angiotensinogen, an α_2-globulin synthesized in the liver, is the substrate for renin and is broken down into the angiotensin peptides. Angiotensinogen consists of 485 amino acids, 33 of which constitute a signal peptide that is cleaved prior to secretion. The action of renin on angiotensinogen produces angiotensin I. Angiotensin I is composed of the first 10 amino acid sequence following the signal peptide and does not have biologic activity. Angiotensin II, the main form of biologically active angiotensin, is formed by cleavage of the two carboxyl-terminal amino acids of angiotensin I by angiotensin-converting enzyme (ACE) (Figure 10–2). ACE is localized to cell membranes in the lung and intracellular granules in certain tissues that produce angiotensin II. Amino peptidase A removes the amino-terminal aspartic acid to produce the heptapeptide, angiotensin III. Angiotensin II and angiotensin III have equivalent efficacy in promoting aldosterone secretion and modifying renal blood flow. The half-life in the circulation of angiotensin II is short (<60 seconds). Elements of the renin-angiotensin-aldosterone system are present in the adrenal glands, the kidneys, the heart, and the brain. For example, the adrenal glomerulosa cells contain the proteins needed to produce and secrete angiotensin II. Other tissues contain one or more components of the renin-angiotensin system and require other cells or circulating components, or both, to generate angiotensin II.


FIGURE 10–1 Renin-angiotensin-aldosterone and potassium-aldosterone feedback loops. Zona glomerulosa aldosterone production and secretion are determined by input from each loop (ACE, angiotensin-converting enzyme; ACTH, corticotropin; ANP, atrial natriuretic peptide; BP, blood pressure; K⁺, potassium; Na⁺, sodium).

Angiotensin II functions through the angiotensin receptor to maintain normal extracellular volume and blood pressure by: (a) increasing aldosterone secretion from the zona glomerulosa by increasing transcription of CYP11B2; (b) constriction of vascular smooth muscle, thereby increasing blood pressure and reducing renal blood flow; (c) enhancing the release of norepinephrine and epinephrine from the adrenal medulla; (d) enhancement of the activity of the sympathetic nervous system by increasing central sympathetic outflow, thereby increasing norepinephrine discharge from sympathetic nerve terminals; and, (e) promotion of the release of vasopressin.

Aldosterone

Aldosterone is produced in the zona glomerulosa of the adrenal cortex. Approximately 50% to 70% of aldosterone circulates bound to either albumin or corticosteroid-binding globulin; 30% to 50% of total plasma aldosterone is free. Aldosterone is rapidly inactivated to tetrahydroaldosterone in the liver and has a half-life of 15 to 20 minutes. Aldosterone regulates extracellular volume and potassium homeostasis by binding to renal cortical collecting duct principal epithelial cell mineralocorticoid receptors (Figure 10–3). The mineralocorticoid receptor—a member of the nuclear receptor family and also found in the heart, colon, and hippocampus—is localized to the cytoplasm prior to activation, undergoes a conformation change on binding to aldosterone, and translocates into the nucleus where it functions as a transcription factor. The aldosterone-regulated serum- and glucocorticoid-inducible kinase appears to be a key intermediary (see Figure 10–3). Aldosterone increases expression of this kinase which phosphorylates and inactivates neural-precursor-cell-expressed, developmentally down regulated (Nedd) 4-2, a ubiquitin ligase which is responsible for degrading the epithelial sodium channel. This, in turn, leads to an increased number of open sodium channels in the luminal membrane of the principal cells in the cortical collecting tubule, resulting in increased sodium ion reabsorption. The sodium loss increases luminal electronegativity, which augments tubular secretion of potassium by the renal tubular cells and hydrogen ion by the renal interstitial cells. Another mediator of the mineralocorticoid receptor transcriptional response is the activation is the sodium-potassium ATPase at the basolateral membrane, which drives the
FIGURE 10–3 Aldosterone regulates extracellular volume and potassium homeostasis by binding to the renal cortical collecting duct principal epithelial cell mineralocorticoid receptor (MR). The activated MR translocates into the nucleus where it binds to the glucocorticoid response element (GRE) and functions as a transcription factor. Aldosterone increases expression of serum- and glucocorticoid-inducible kinase (Sgk1), which phosphorylates and inactivates neural-precursor-cell-expressed, developmentally downregulated gene (Nedd) 4-2, a ubiquitin ligase which is responsible for degrading the epithelial sodium channel (ENaC). Another mediator of mineralocorticoid receptor transcriptional response is the activation is the sodium-potassium ATPase (Na^+/K^+ ATPase) at the basolateral membrane, which drives the uptake of potassium and export of sodium. Although glucocorticoids and mineralocorticoids bind equally to the mineralocorticoid receptor, specificity of action is due to the glucocorticoid-degrading enzyme, 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which prevents glucocorticoids from interacting with the receptor. (Adapted with permission from Odermatt A, Atanasov AG. Mineralocorticoid receptors: emerging complexity and functional diversity. *Steroids.* 2009 Feb;74(2):163-171.)

uptake of potassium and export of sodium (see Figure 10–3). Although glucocorticoids and mineralocorticoids bind equally to the mineralocorticoid receptor, specificity of action is due to the glucocorticoid-degrading enzyme, 11β-hydroxysteroid dehydrogenase, which is strongly expressed in the kidney and prevents glucocorticoids from interacting with the receptor.

Aldosterone has nonclassic effects that, although probably genomic and therefore mediated by activation of the cytosolic mineralocorticoid receptor, do not include modification of sodium-potassium balance. Aldosterone-mediated actions include: the expression of several collagen genes; activation of genes controlling tissue growth factors, such as transforming growth factor β and plasminogen activator inhibitor type 1; and, increased expression of genes mediating inflammation. The resultant actions lead to microangiopathy, necrosis (acutely), and fibrosis in various tissues such as the heart, the vasculature, and the kidney. Increased levels of aldosterone are not necessary to cause this damage; an imbalance between the volume or sodium balance state and the level of aldosterone appear to be the critical factors. Spironolactone and eplerenone are mineralocorticoid receptor antagonists. Mineralocorticoid receptor blockade has proven to be clinically important in patients with cardiovascular disease. For example, when spironolactone was added to the treatment program for patients with New York Heart Association class IV heart failure or class III heart failure, it resulted in a significant 30% reduction in overall mortality due to reductions in death from heart failure and sudden death. When eplerenone was added to the treatment program for patients who had a myocardial infarction 3 to 14 days previously and had a left ventricular ejection fraction of less than or equal to 40%, it resulted in a significantly lower rate of cardiovascular mortality and sudden cardiac death. The effect of mineralocorticoid receptor antagonists on survival in patients with primary aldosteronism has not yet been studied.

The action of angiotensin II on aldosterone synthesis and secretion involves a feedback loop that also includes extracellular fluid volume (see Figure 10–1). A decrease in circulating blood volume results in decreased renal perfusion pressure that is detected by the renal juxtaglomerular cells. Activation of the juxtaglomerular cells increases renin release, which catalyzes the conversion of angiotensinogen to angiotensin I. ACE in the pulmonary and renal endothelium catalyzes the conversion of angiotensin I to angiotensin II and III, which act on the adrenal zona glomerulosa angiotensin receptor to stimulate aldosterone release. Aldosterone acts at the renal mineralocorticoid receptors to stimulate sodium and water retention to preserve the circulating blood volume. Renin release can also be triggered by catecholamines, hypokalemia, and a decrease in sodium chloride absorption in the macula densa cells. Aldosterone secretion can be directly stimulated by ACTH and hyperkalemia. Thus, sodium restriction activates and sodium overload suppresses the renin-angiotensin-aldosterone axis. Mineralocorticoid escape refers to the counterregulatory mechanisms that occur after 3 to 5 days of excessive mineralocorticoid administration. Several mechanisms contribute to this escape, including renal hemodynamic factors and increased release of ANP.

Excess aldosterone secretion causes hypertension through two main mechanisms: (1) mineralocorticoid-induced expansion of plasma and extracellular fluid volume; and (2) increase in total peripheral vascular resistance.

PRIMARY ALDOSTERONISM

Hypertension, suppressed plasma renin activity (PRA), and increased aldosterone secretion characterize the syndrome of primary aldosteronism. Aldosterone-producing adenoma (APA) and bilateral idiopathic hyperaldosteronism (IHA) are the two most common subtypes of primary aldosteronism (Table 10–2). Somatic mutations account for about half of APAs and include mutations in genes encoding components of: the Kir 3.4 (GIRK4) potassium channel (KCNJ5); the sodium/potassium and calcium ATPases (ATP1A1 and ATP2B3); and a voltage-dependent C-type calcium channel (CACNA1D). A much less common form, unilateral hyperplasia, is caused by micronodular or macronodular

TABLE 10–2 Adrenocortical causes of hypertension.

Low Renin and High Aldosterone
PRIMARY ALDOSTERONISM
Aldosterone-producing adenoma (APA) ≈35% of cases
Bilateral idiopathic hyperplasia (IHA) ≈60% of cases
Unilateral (primary) adrenal hyperplasia ≈2% of cases
Aldosterone-producing adrenocortical carcinoma <1% of cases
Familial hyperaldosteronism (FH)
    Glucocorticoid-remediable aldosteronism (FH type I) <1% of cases
    FH type II (APA or IHA) <2% of cases
    FH type III (associated with the germline mutation in the KCNJ5 potassium channel): <1% of cases
Ectopic aldosterone-producing adenoma or carcinoma <0.1% of cases

Low Renin and Low Aldosterone
HYPERDEOXYCORTICOSTERONISM

        Unilateral adrenal disease
        Bilateral adrenal disease
            Bilateral macronodular adrenal hyperplasia (rare)
            Primary pigmented nodular adrenal disease (rare)

Abbreviations: ACTH, corticotropin; AME, apparent mineralocorticoid excess; APA, aldosterone-producing adenoma; FH, familial hyperaldosteronism; IHA, idiopathic hyperaldosteronism.

hyperplasia of the zona glomerulosa of predominantly one adrenal gland. Unilateral hyperplasia is referred to as primary adrenal hyperplasia (PAH). Familial hyperaldosteronism (FH) is also rare and three types have been described: FH types 1, 2, and 3.

FH type 1, or glucocorticoid-remediable aldosteronism (GRA), is caused by a chimeric gene duplication that results from unequal crossing over between the promoter sequence of *CYP11B1* gene (encoding 11β-hydroxylase) and the coding sequence of CYP11B2 (encoding aldosterone synthase). This chimeric gene contains the 3' ACTH-responsive portion of the promoter from the 11β-hydroxylase gene fused to the 5' coding sequence of the aldosterone synthase gene. The result is ectopic expression of aldosterone synthase activity in the cortisol-producing zona fasciculata. Thus, mineralocorticoid production is regulated by ACTH instead of the normal secretagogue, angiotensin II. Aldosterone secretion can be suppressed by glucocorticoid therapy.

FH type 2 (FH-2) refers to the familial occurrence of APA or IHA or both. FH-2 is autosomal dominant and may be monogenic. The hyperaldosteronism in FH-2 does not suppress with dexamethasone, and GRA mutation testing is negative. FH-2 is more common than FH-1, but it still accounts for fewer than 3% of all patients with primary aldosteronism. The molecular basis for FH-2 is unclear, although a linkage analysis study showed an association with chromosomal region 7p22.

FH-3 was first described in a single family in 2008. This initial report included a father and two daughters who all presented with refractory hypertension before age 7 years and all three were treated with bilateral adrenalectomy. The adrenal glands showed massive hyperplasia. Three years later the causative germline mutation in this family was discovered: a point mutation in and near the selectivity filter of the potassium channel *KCNJ5*. This *KCNJ5* mutation produces increased sodium conductance and cell depolarization, triggering calcium entry into glomerulosa cells, the signal for aldosterone production and cell proliferation. Other families with early onset hyperaldosteronism have also been identified to have germline point mutations in the *KCNJ5* gene.

Prevalence

In the past, clinicians would not consider the diagnosis of primary aldosteronism unless the patient presented with spontaneous hypokalemia, and then the diagnostic evaluation would require discontinuing antihypertensive medications for at least 2 weeks. The *spontaneous hypokalemia/no antihypertensive drug* diagnostic approach resulted in predicted prevalence rates of less than 0.5% of hypertensive patients. However, it is now recognized that most patients with primary aldosteronism are not hypokalemic and that case-detection testing can be completed with a simple blood test (plasma aldosterone concentration [PAC]-to-plasma renin activity [PRA] ratio) while the patient is taking most antihypertensive drugs. Using the PAC-PRA ratio as a case-detection test, followed by aldosterone suppression confirmatory testing, has resulted in much higher prevalence estimates (5%-10% of all patients with hypertension) for primary aldosteronism.

Clinical Presentation

The diagnosis of primary aldosteronism is usually made in patients who are in the third to sixth decade of life. Few symptoms are specific to the syndrome. Patients with marked hypokalemia may have muscle weakness and cramping, headaches, palpitations, polydipsia, polyuria, nocturia, or a combination of these. Periodic paralysis is a very rare presentation in Caucasians, but it is not an infrequent presentation in patients of Asian descent. The polyuria and nocturia are a result of a hypokalemia-induced renal concentrating defect and the presentation is frequently mistaken for prostatism in men. There are no specific physical findings. Edema is not a common finding because of mineralocorticoid escape. The degree of hypertension is usually moderate to severe and may be resistant to usual pharmacologic treatments. Although not common, primary aldosteronism may present with hypertensive urgencies. Patients with APA tend to have higher blood pressures than those with IHA. Hypokalemia is frequently absent; thus, all patients with hypertension are candidates for this disorder. In other patients, the hypokalemia only becomes evident with addition of a potassium-wasting diuretic (eg, hydrochlorothiazide, furosemide). Aldosterone excess also leads to a mild metabolic alkalosis because of increased urinary hydrogen excretion mediated both by hypokalemia and by the direct stimulatory effect of aldosterone on distal renal tubule acidification. Because of a reset osmostat, the serum sodium concentration tends to be high-normal or slightly above the upper limit of normal—this clinical finding is very useful when initially assessing the potential for primary aldosteronism.

Several studies have shown that patients with primary aldosteronism may be at higher risk than other patients with hypertension for target organ damage of the heart and kidney. When matched for age, blood pressure, and duration of hypertension, patients with primary aldosteronism have greater left ventricular mass by echocardiographic measurements than patients with other types of hypertension (eg, pheochromocytoma, Cushing syndrome, or essential hypertension). In patients with APA, the left ventricular wall thickness and mass decreases markedly 1 year after adrenalectomy. Patients presenting with either APA or IHA have a significantly higher rate of cardiovascular events (eg, stroke, atrial fibrillation, and myocardial infarction) than matched patients with essential hypertension who have similar degrees of hypertension duration and control.

Diagnosis

The diagnostic approach to primary aldosteronism can be considered in three parts: (A) case-detection tests, (B) confirmatory tests, and (C) subtype evaluation tests.

A. Case-detection tests Spontaneous hypokalemia is uncommon in patients with uncomplicated hypertension and, when present, strongly suggests associated mineralocorticoid excess. However, most patients with primary aldosteronism have baseline serum levels of potassium in the normal range. Therefore, hypokalemia is not and should not be the only criterion

Consider testing for primary aldosteronism in the following settings:
• Hypertension and hypokalemia
• Resistant hypertension (three drugs and poor BP control)
• Adrenal incidentaloma and hypertension
• Onset of hypertension at a young age (<30 y)
• Severe hypertension (≥150 mm Hg systolic or ≥100 mm Hg diastolic)
• Whenever considering secondary hypertension

Case-detection testing:
Morning blood sample in seated ambulant patient
• Plasma aldosterone concentration (PAC)
• Plasma renin activity (PRA) or plasma renin concentration (PRC)

↑ PAC (≥15 ng/dL; ≥416 pmol/L)
↓ PRA (<1.0 ng/mL/h)
and
PAC-PRA ratio ≥20 ng/dL per ng/mL/h (≥555 pmol/L per ng/mL/h)

Confirmatory testing

FIGURE 10–4 When to consider testing for primary aldosteronism and use of the plasma aldosterone concentration to plasma renin activity ratio as a case-finding tool (BP, blood pressure; PAC, plasma aldosterone concentration; PRA, plasma renin activity; PRC, plasma renin concentration).

used to determine whom to test for primary aldosteronism. Patients with hypertension and hypokalemia (regardless of presumed cause), treatment-resistant hypertension (three antihypertensive drugs and poor control), severe hypertension (≥150 mm Hg systolic or ≥100 mm Hg diastolic), hypertension and an incidental adrenal mass, and onset of hypertension at a young age (eg, <30 years) should undergo case-detection testing for primary aldosteronism (Figure 10–4). In addition, primary aldosteronism should be tested for when considering a secondary hypertension evaluation (eg, when testing for renovascular disease or pheochromocytoma).

In patients with suspected primary aldosteronism, case detection can be accomplished by measuring a morning (preferably between 8 AM and 10 AM) ambulatory paired random PAC and PRA (see Figure 10–4). This test may be performed while the patient is taking most antihypertensive medications and without posture stimulation. Hypokalemia reduces the secretion of aldosterone, and it is optimal in patients with hypokalemia to restore the serum level of potassium to normal before performing diagnostic studies. It may be difficult to interpret data obtained from patients treated with a mineralocorticoid receptor antagonist (spironolactone and eplerenone). These drugs prevent aldosterone from activating the receptor, resulting sequentially in sodium loss, a decrease in plasma volume, and an elevation in PRA, which will reduce the utility of the PAC/PRA ratio. For this reason, spironolactone and eplerenone should not be initiated until the evaluation is completed, and the final decisions about treatment are made. However, there are rare exceptions to this rule. For example, if the patient is hypokalemic despite treatment

with spironolactone or eplerenone, then the mineralocorticoid receptors are not fully blocked, and PRA should be suppressed in such a patient with primary aldosteronism. In this unique circumstance, the evaluation for primary aldosteronism can proceed, despite treatment with mineralocorticoid receptor antagonists. However, in most patients already receiving spironolactone, therapy should be discontinued for at least 6 weeks. Other potassium-sparing diuretics, such as amiloride and triamterene, usually do not interfere with testing unless the patient is on high doses.

ACE-inhibitors and angiotensin receptor blockers (ARBs) have the potential to falsely elevate PRA. Therefore, in a patient treated with an ACE inhibitor or ARB, the finding of a detectable PRA level or a low PAC-PRA ratio does not exclude the diagnosis of primary aldosteronism. However, a very useful clinical point is that when a PRA level is undetectably low in a patient taking an ACE inhibitor or ARB, primary aldosteronism is likely. A second important clinical point is that PRA is suppressed (<1.0 ng/mL/h) in almost all patients with primary aldosteronism, regardless of concurrent medications.

The PAC-PRA ratio is based on the concept of paired hormone measurements. For example, in a hypertensive hypokalemic patient: (a) secondary hyperaldosteronism should be considered when both PRA and PAC are increased and the PAC-PRA ratio is less than 10 (eg, renovascular disease); (b) an alternate source of mineralocorticoid receptor agonism should be considered when both PRA and PAC are suppressed (eg, hypercortisolism); and, (c) primary aldosteronism should be suspected when PRA is suppressed (<1.0 ng/mL/h) and PAC is increased (Figure 10–5). Although there is some uncertainty about test characteristics and lack of standardization, the PAC-PRA ratio is widely accepted as the case-detection test of choice for primary aldosteronism. It is important to understand that the lower limit of detection varies among different PRA assays and can have a dramatic effect on the PAC-PRA ratio. As an example, if the lower limit of detection for PRA is 0.6 ng/mL/h and the PAC is 18 ng/dL, then the PAC-PRA ratio would be 30; however, if the lower limit of detection for PRA is 0.1 ng/mL/h and the PAC is 18 ng/dL, then the PAC-PRA ratio would be 180. Thus, the cutoff for a high PAC-PRA ratio is laboratory dependent and, more specifically, PRA assay dependent. At Mayo Clinic, a PAC (in ng/dL)-PRA (in ng/mL/h) ratio of 20 or more and PAC of at least 15 ng/dL are found in more than 90% of patients with surgically confirmed APA. In patients without primary aldosteronism, most of the variation occurs within the normal range. The sensitivity and specificity of the PAC-PRA ratio in the diagnosis of primary aldosteronism are approximately 80% and 75%, respectively. A high PAC-PRA ratio with a PAC of at least 15 ng/dL is a positive case-detection test result, a finding that warrants further testing. Other initial case-detection strategies include measurement of isolated plasma renin activity or 24-hour urinary aldosterone excretion.

B. Confirmatory tests   An increased PAC-PRA ratio is not diagnostic by itself, and primary aldosteronism must be confirmed by demonstrating lack of normal suppressibility of aldosterone secretion. The list of drugs and hormones capable of affecting the

(Adapted with permission from Young WF Jr, Hogan MJ. Renin-independent hypermineralocorticoidism. *Trends Endocrinol Metab.* 1994 Apr;5(3):97-106.)

renin-angiotensin-aldosterone axis is extensive, and frequently, a medication-contaminated evaluation is unavoidable. Calcium channel blockers and α_1-adrenergic receptor blockers do not affect the diagnostic accuracy in most cases. It is impossible to interpret data obtained from patients receiving treatment with mineralocorticoid receptor antagonists (eg, spironolactone, eplerenone) when PRA is not suppressed. Therefore, treatment with a mineralocorticoid receptor antagonist should not be initiated until the evaluation has been completed and the final decisions about treatment have been made. Aldosterone suppression testing can be performed with orally administered sodium chloride and measurement of urinary aldosterone or with intravenous sodium chloride loading and measurement of PAC.

a. **Oral sodium loading test**—After hypertension and hypokalemia are controlled, patients should receive a high sodium diet (supplemented with sodium chloride tablets if needed) for 3 days, with a goal sodium intake of 5000 mg (equivalent to 12.8 g sodium chloride or 218 mEq of sodium). The risk of increasing dietary sodium in patients with severe hypertension must be assessed in each case. Because the high sodium diet can increase kaliuresis and hypokalemia, vigorous replacement of potassium chloride may be needed, and the serum level of potassium should be monitored daily. On the third day of the high sodium diet, a 24-hour urine specimen is collected for measurement of aldosterone, sodium, and creatinine. To document adequate sodium repletion, the 24-hour urinary sodium excretion should exceed 200 mEq. Urinary aldosterone excretion more than 12 µg/24 h is consistent with autonomous aldosterone secretion. The sensitivity and specificity of the oral sodium loading test are 96% and 93%, respectively.

b. **Intravenous saline infusion test**—The intravenous saline infusion test has also been used for the confirmation of primary aldosteronism. Normal subjects show suppression of PAC after volume expansion with isotonic saline; subjects with primary aldosteronism do not show this suppression. The risks associated with rapid intravenous volume expansion should be assessed in each case. The test is done after an overnight fast. Two liters of 0.9% sodium chloride solution are infused intravenously with an infusion pump over 4 hours into the recumbent patient. Blood pressure and heart rate are monitored during the infusion. At the completion of the infusion, blood is drawn for measurement of PAC. PAC levels in normal subjects decrease to less than 5 ng/dL; most patients with primary aldosteronism do not suppress to less than 10 ng/dL; post-saline infusion PAC values between 5 and 10 ng/dL are indeterminate and can be seen in patients with IHA.

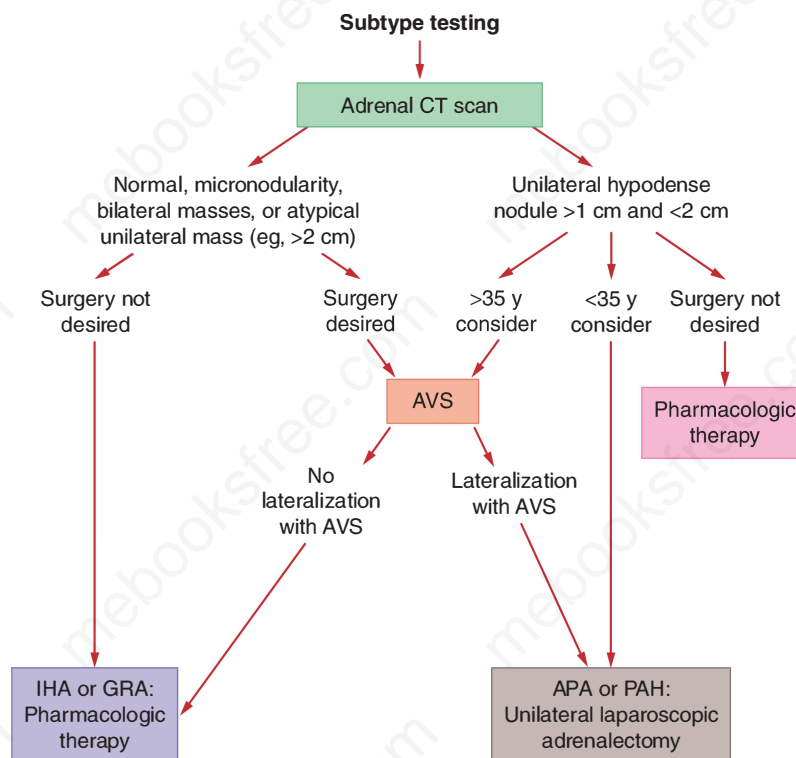
C. Subtype studies   Following case detection and confirmatory testing, the third management step guides the therapeutic approach by distinguishing APA and PAH from IHA and GRA. Unilateral adrenalectomy in patients with APA or PAH results in normalization of hypokalemia in all; hypertension is improved in all and is cured in approximately 30% to 60% of them. In IHA and GRA, unilateral or bilateral adrenalectomy seldom corrects the hypertension. IHA and GRA should be treated medically. APA is found in approximately 35% of cases and bilateral IHA in approximately 60% of cases (see Table 10–2). APAs are usually hypodense nodules (<2 cm in diameter) on CT and are golden yellow in color on cut section. IHA adrenal glands may be normal on CT or show nodular changes. Aldosterone-producing adrenal carcinomas are almost always greater than 4 cm in diameter and have a suspicious imaging phenotype on CT. Patients with aldosterone-producing adrenocortical carcinomas usually have severe aldosterone excess with serum potassium concentrations frequently less than 2.0 mEq/L.


FIGURE 10–6 Subtype evaluation of primary aldosteronism. For patients who want to pursue a surgical treatment for their hypertension, adrenal venous sampling is frequently a key diagnostic step. See text for details (APA, aldosterone-producing adenoma; AVS, adrenal venous sampling; CT, computed tomography; IHA, idiopathic hyperaldosteronism; PAH, primary adrenal hyperplasia). (Adapted with permission from Young WF Jr, Hogan MJ. Renin-independent hypermineralocorticoidism. *Trends Endocrinol Metab*. 1994 Apr;5(3):97-106.)

a. **Adrenal CT**—Primary aldosteronism subtype evaluation may require one or more tests, the first of which is imaging the adrenal glands with CT (Figure 10–6). This imaging test is usually ordered as CT of the abdomen limited to the adrenal glands with 2-mm contiguous cuts. Although contrast enhancement is not necessary, contrast administration results in improved discrimination between normal adrenal cortex and the small lipid-rich cortical adenoma. When a solitary unilateral hypodense (Hounsfield units [HU] <10) macroadenoma (>1 cm) and normal contralateral adrenal morphology are found on CT in a young patient (adrenal incidentalomas are uncommon in patients <35 years) with primary aldosteronism, unilateral adrenalectomy is a reasonable therapeutic option (Figure 10–7). However, in most cases, CT may show normal-appearing adrenals, minimal unilateral adrenal limb thickening, unilateral microadenomas (<1 cm), bilateral macroadenomas, or a large (eg, >2 cm) unilateral macroadenomas that would be atypical for primary aldosteronism. In these cases, when the patient wants to pursue the surgical treatment option for primary aldosteronism, additional testing is required to determine the source of excess aldosterone secretion (Figure 10–8). Small APAs may be labeled incorrectly as IHA on the basis of CT findings of bilateral nodularity or normal-appearing adrenals. Also, apparent adrenal microadenomas may actually represent areas of hyperplasia, and unilateral adrenalectomy would be inappropriate. In addition, nonfunctioning unilateral adrenal macroadenomas are not uncommon, especially in individuals more than 35 years of age.

Unilateral PAH may be visible on CT or the PAH adrenal may appear normal on CT. In general, patients with APAs have more severe hypertension, more frequent hypokalemia, higher plasma (>30 ng/dL) and urinary (>30 µg/24 h) levels of aldosterone than those with IHA.

Adrenal CT is not accurate in distinguishing between APA and IHA. In one study of 203 patients with primary aldosteronism who were evaluated with both CT and adrenal venous sampling (AVS), CT was accurate in only 53% of patients; based on CT findings, 42 patients (22%) would have been incorrectly excluded as candidates for adrenalectomy and 48 (25%) might have had unnecessary or inappropriate surgery. Therefore, AVS is essential to direct appropriate therapy in patients older than 35 years of age with primary aldosteronism who have a high probability of APA and who seek a potential surgical cure. However, it is important to recognize that the surgical option is not mandatory in patients with APA—pharmacologic therapy with a mineralocorticoid receptor antagonist is the medication equivalent of adrenalectomy (discussed later).

b. **Adrenal venous sampling**—AVS is the criterion standard test to distinguish between unilateral and bilateral disease in patients with primary aldosteronism who want to pursue surgical management for their hypertension. AVS is an intricate procedure because the right adrenal vein is small and may be difficult to locate and cannulate—the success rate depends on the proficiency of the angiographer. The five keys to a successful AVS program are: (1) appropriate patient selection; (2) careful patient preparation; (3) focused
FIGURE 10–7 A 30-year-old woman had a 7-year history of hypertension and hypokalemia. Her blood pressure was not well controlled despite a four-drug program that included a calcium channel blocker, ACE-inhibitor, thiazide diuretic, and a β-adrenergic blocker. To correct her hypokalemia, she took 420 mEq of potassium per day. The case-detection test for primary aldosteronism was positive, with a plasma aldosterone concentration (PAC) of 34 ng/dL and low plasma renin activity (PRA) at less than 0.6 ng/mL/h (PAC-PRA ratio >56). The confirmatory test for primary aldosteronism was also positive, with 24-hour urinary excretion of aldosterone of 77 µg on a high-sodium diet (urinary sodium, 205 mEq/24 h). **A.** Adrenal CT axial image showing a 15-mm low-density mass (arrow) within the right adrenal gland. She underwent laparoscopic right adrenalectomy. **B.** Right adrenal gland (6.2 g, 6.1 cm × 3.7 cm × 1.4 cm) with a 1.8-cm cortical adenoma arising from the surface. **C.** Cut sections of the yellow adrenal cortical adenoma forming a 1.8 cm × 1.7 cm × 1.3 cm nodule. The postoperative plasma aldosterone concentration was less than 1.0 ng/dL. Hypokalemia was resolved. Four years after surgery, her blood pressure was normal without the aid of antihypertensive medications.

technical expertise; (4) defined protocol; and, (5) accurate data interpretation. A center-specific, written protocol is mandatory. The protocol should be developed by an interested group of endocrinologists, hypertension specialists, internists, radiologists, and laboratory personnel. Safeguards should be in place to prevent mislabeling of the blood tubes in the radiology suite and to prevent sample mix-up in the laboratory. At Mayo Clinic, we use continuous cosyntropin infusion during AVS (50 µg/h started 30 minutes before sampling and continued throughout the procedure) for the following reasons: (a) to minimize stress-induced fluctuations in aldosterone secretion during nonsimultaneous AVS; (b) to maximize the gradient in cortisol from adrenal vein to inferior vena cava (IVC) and thus confirm successful sampling of the adrenal veins; and, (c) to maximize the secretion of aldosterone from an APA. The adrenal veins are catheterized through the percutaneous femoral vein approach, and the position of the catheter tip is verified by gentle injection of a small amount of nonionic contrast medium and radiographic documentation (see Figure 10–8). Blood is obtained from both adrenal veins and the IVC below the renal veins and assayed for aldosterone and cortisol concentrations. To be sure there is no cross-contamination, the IVC sample should be obtained from the external iliac vein. The venous sample from the left side typically is obtained from the common phrenic
Bilateral adrenal venous sampling

Vein	Aldosterone (A), ng/dL	Cortisol (C), μg/dL	A/C ratio	Aldosterone ratio*
R adrenal vein	8450	1669	5.1	8.5

Inferior vena cava	13	22	0.6	

*R adrenal vein A/C ratio divided by L adrenal vein A/C ratio.

C

FIGURE 10–8 A 48-year-old man had a 7-year history of hypertension that was not optimally controlled on four antihypertensive drugs (β-adrenergic blocker, peripheral α$_1$-antagonist, angiotensin receptor blocker, and a thiazide diuretic). He was not hypokalemic. Resistant hypertension prompted case-detection testing for primary aldosteronism with a plasma aldosterone concentration (PAC) of 15 ng/dL and low plasma renin activity (PRA) at less than 0.6 ng/mL/h (PAC-PRA ratio >25). The confirmatory test for primary aldosteronism was also positive, with 24-hour urinary excretion of aldosterone of 16 μg on a high-sodium diet (urinary sodium, 356 mEq/24 h). **A.** Adrenal CT split section axial images show a 12-mm thickening (large arrow) in the inferior aspect of the left adrenal gland and a tiny nodule (small arrow) in the right adrenal gland. The patient wanted to pursue a surgical approach to the resolution of or improvement in hypertension. **B.** Adrenal venous sampling images showing the catheter in the right and left adrenal veins. The delicate venous architecture is demonstrated. **C.** Adrenal venous sampling lateralized aldosterone secretion to the right adrenal gland, and a 3-mm yellow cortical adenoma was found at laparoscopic right adrenalectomy. The postoperative plasma aldosterone concentration was less than 1.0 ng/dL. One year after surgery, his blood pressure was in the normal range with the aid of one antihypertensive medication. (Reproduced with permission from Young WF. Endocrine hypertension: then and now. *Endocr Pract*. 2010 Sep-Oct;16(5):888-902.)

vein immediately adjacent to the entrance of the adrenal vein. The cortisol concentrations from the adrenal veins and IVC are used to confirm successful catheterization; the adrenal vein-IVC cortisol ratio is typically more than 10:1.

Dividing the right and left adrenal vein PACs by their respective cortisol concentrations corrects for the dilutional effect of the inferior phrenic vein flow into the left adrenal vein; these are termed **cortisol-corrected ratios** (see Figure 10–8). In patients with APA, the mean cortisol-corrected aldosterone ratio (APA-side PAC/cortisol:normal adrenal PAC/cortisol) is 18:1. A cutoff of the cortisol-corrected aldosterone ratio from high side to low side more than 4:1 is used to indicate unilateral aldosterone excess (see Figure 10–8). In patients with IHA, the mean cortisol-corrected aldosterone ratio is 1.8:1 (high side:low side); a ratio less than 3:1 is suggestive of bilateral aldosterone hypersecretion. Therefore, most patients with a unilateral source of aldosterone will have cortisol-corrected aldosterone

lateralization ratios greater than 4.0; ratios greater than 3.0 but less than 4.0 represent a zone of overlap. Ratios no more than 3.0 are consistent with bilateral aldosterone secretion. The test characteristics of AVS for detecting unilateral aldosterone hypersecretion (APA or PAH) have sensitivity of 95% and specificity of 100%. However, since all patients who undergo AVS are not sent to surgery, the true diagnostic sensitivity of AVS is unknown. At centers with experience with AVS, the complication rate is 2.5% or less. Complications can include symptomatic groin hematoma, adrenal hemorrhage, and dissection of an adrenal vein.

Some centers and clinical practice guidelines recommend that AVS should be performed in all patients who have the diagnosis of primary aldosteronism. However, a more practical approach is to consider the use of AVS based on patient preferences, patient age, clinical comorbidities, and clinical probability of finding an APA (see Figure 10–6).

c. **Glucocorticoid-remediable aldosteronism—familial hyperaldosteronism type 1**—In the absence of glucocorticoid therapy, this mutation results in overproduction of aldosterone and the hybrid steroids 18-hydroxycortisol and 18-oxycortisol, which can be measured in the urine to make the diagnosis. Genetic testing is a sensitive and specific means of diagnosing GRA and obviates the need to measure the urinary levels of 18-oxocortisol and 18-hydroxycortisol or to perform dexamethasone suppression testing. Genetic testing for GRA should be considered for primary aldosteronism patients with a family history of primary aldosteronism or onset of primary aldosteronism at a young age (eg, <20 years), or in primary aldosteronism patients who have a family history of strokes at a young age. Cerebrovascular complications (eg, hemorrhagic stroke) associated with intracranial aneurysms affect approximately 20% of all patients with GRA—a frequency of cerebral aneurysm similar to that found in adult polycystic kidney disease.

d. **Familial hyperaldosteronism type 2**—FH type 2 is autosomal dominant and may be monogenic. All hypertensive first degree relatives of patients with primary aldosteronism should be advised to have case detection testing for primary aldosteronism.

e. **Familial hyperaldosteronism type 3**—FH type 3 typically presents in childhood or adolescence with hypertension, which may be mild or severe. When hypertension is severe, spontaneous hypokalemia is more likely to be present. FH-3 is caused by germline mutations in the potassium channel *KCNJ5*. Germline mutation testing is available and should be considered in patients with familial hyperaldosteronism and in patients who present with primary aldosteronism in childhood or adolescence.

Treatment

The treatment goal is to prevent the morbidity and mortality associated with hypertension, hypokalemia, and cardiovascular damage. The cause of the primary aldosteronism helps to determine the appropriate treatment. Normalization of blood pressure should not be the only goal in managing a patient who has primary aldosteronism. In addition to the kidney and colon, mineralocorticoid receptors occur in the heart, brain, and blood vessels. Excessive secretion of aldosterone is associated with increased risk of cardiovascular disease and morbidity. Therefore, normalization of circulating aldosterone or mineralocorticoid receptor blockade should be part of the management plan for all patients with primary aldosteronism. However, clinicians must understand that most patients with longstanding primary aldosteronism have some degree of renal insufficiency that is masked by the glomerular hyperfiltration associated with aldosterone excess. The true degree of renal insufficiency may only become evident after effective pharmacologic or surgical therapy.

A. Surgical treatment of aldosterone-producing adenoma and unilateral hyperplasia Unilateral laparoscopic adrenalectomy is an excellent treatment option for patients with APA or PAH (unilateral hyperplasia). Although blood pressure control improves in nearly 100% of patients postoperatively, average long-term cure rates of hypertension after unilateral

adrenalectomy for APA range from 30% to 60%. Persistent hypertension following adrenalectomy is correlated directly with having more than one first-degree relative with hypertension, use of more than two antihypertensive agents preoperatively, older age, increased serum creatinine level, and duration of hypertension.

Laparoscopic adrenalectomy is the preferred surgical approach and is associated with shorter hospital stays and less long-term morbidity than the open approach. Because APAs are small and may be multiple, the entire adrenal gland should be removed. To decrease the surgical risk, hypokalemia should be corrected with potassium supplements and/or a mineralocorticoid receptor antagonist preoperatively. The mineralocorticoid receptor antagonist and potassium supplements should be discontinued postoperatively. PAC should be measured 1 to 2 days after the operation to confirm a biochemical cure. Serum potassium levels should be monitored weekly for 4 weeks after surgery and a generous sodium diet should be followed to avoid the hyperkalemia of hypoaldosteronism that may occur because of the chronic suppression of the renin-angiotensin-aldosterone axis. In approximately 5% of APA patients, clinically significant hyperkalemia may develop after surgery, and short-term fludrocortisone supplementation may be required. Typically, the component of hypertension that was associated with aldosterone excess resolves in 1 to 3 months postoperatively.

B. Pharmacologic treatment IHA should be treated medically. In addition, patients with APAs may be treated medically if the medical treatment includes mineralocorticoid receptor blockade. A sodium-restricted diet (<100 mEq of sodium per day), maintenance of ideal body weight, tobacco avoidance, and regular aerobic exercise contribute significantly to the success of pharmacologic treatment. No placebo-controlled randomized trials have evaluated the relative efficacy of drugs in the treatment of primary aldosteronism. Spironolactone, available as 25-, 50-, and 100-mg tablets, has been the drug of choice to treat primary aldosteronism for more than 4 decades. The initial dosage is 12.5 to 25 mg/d and is increased to 400 mg/d, if necessary, to achieve a high-normal serum potassium concentration without the aid of oral potassium chloride supplementation. Hypokalemia responds promptly, but hypertension may take as long as 4 to 8 weeks to correct. After several months of therapy, this dosage often can be decreased to as little as 25 to 50 mg/d; dosage titration is based on a goal serum potassium level in the high-normal range. Serum potassium and creatinine should be monitored frequently during the first 4 to 6 weeks of therapy (especially in patients with renal insufficiency or diabetes mellitus). Spironolactone increases the half-life of digoxin, and for patients taking this drug, the dosage may need to be adjusted when treatment with spironolactone is started. Concomitant therapy with salicylates should be avoided because they interfere with the tubular secretion of an active metabolite and decrease the effectiveness of spironolactone. Spironolactone is not selective for the mineralocorticoid receptor. For example, antagonism at the androgen receptor may result in painful gynecomastia, erectile dysfunction, and decreased libido in men; agonist activity at the progesterone receptor results in menstrual irregularity in women.

Eplerenone is a steroid-based antimineralocorticoid that acts as a competitive and selective mineralocorticoid receptor antagonist. It has a marked reduction in progestational and antiandrogenic actions compared with spironolactone. Eplerenone is available as 25- and 50-mg tablets. For primary aldosteronism, it is reasonable to start with a dose of 25 mg twice daily (twice daily because of the shorter half-life of eplerenone compared to spironolactone) and titrated upward for a target high-normal serum potassium concentration without the aid of potassium supplements. Potency studies with eplerenone show 50% less milligram per milligram potency when compared with spironolactone. As with spironolactone, it is important to follow blood pressure, serum potassium, and serum creatinine levels closely.

Patients with IHA frequently require a second antihypertensive agent to achieve adequate blood pressure control. Hypervolemia is a major reason for resistance to drug therapy, and low doses of a thiazide (eg, 12.5-50 mg of hydrochlorothiazide daily) or a related sulfonamide diuretic are effective in combination with the mineralocorticoid receptor antagonist. Because these agents often lead to further hypokalemia, serum potassium levels should be monitored.

Before initiating treatment, GRA should be confirmed with genetic testing. In the GRA patient, chronic treatment with physiologic doses of a glucocorticoid normalizes blood pressure and corrects hypokalemia. The clinician should avoid iatrogenic Cushing syndrome with excessive doses of glucocorticoids, especially with the use of dexamethasone in children. The smallest effective dose of shorter acting agents, such as prednisone or hydrocortisone, should be prescribed in relation to body surface area (eg, hydrocortisone, 10-12 mg/m^2/d). Target blood pressure in children should be guided by age-specific blood pressure percentiles. Children should be monitored by pediatricians with expertize in glucocorticoid therapy, with careful attention paid to preventing retardation of linear growth by overtreatment. Treatment with mineralocorticoid receptor antagonists in these patients may be just as effective and avoids the potential disruption of the hypothalamic-pituitary-adrenal axis and risk of iatrogenic side effects. In addition, glucocorticoid therapy or mineralocorticoid receptor blockade may even have a role in normotensive GRA patients.

Patients with FH-3 should be treated with mineralocorticoid receptor blockade. Some of these patients have severe aldosterone excess, and the daily required dosage of spironolactone or eplerenone is not feasible lifelong, and bilateral adrenalectomy may need to be considered in selected cases.

C. Pregnancy   Primary aldosteronism is uncommon in pregnancy with fewer than 40 patients reported in the medical literature, and most patients have had APA. Primary aldosteronism can lead to intrauterine growth retardation, preterm delivery, intrauterine fetal demise, and placental abruption. Case detection testing for primary aldosteronism in the pregnant woman is the same as for nonpregnant patients: morning blood sample for the measurement of aldosterone and plasma renin activity or renin mass measurement. If spontaneous hypokalemia in present in the woman with high aldosterone and suppressed renin, confirmatory testing is not needed. In the normokalemic woman with a positive case detection test, confirmatory testing should be pursued. However, the captopril stimulation test is contraindicated in pregnancy, and the saline infusion test may not be well tolerated. One option is measurement of sodium and aldosterone in a 24-hour urine collection on an ambient sodium diet.

Subtype testing with abdominal MRI without gadolinium is the test of choice. Adrenal imaging with CT, iodocholesterol scintigraphy, and adrenal venous sampling should be avoided in pregnancy.

Primary aldosteronism in pregnancy is fascinating in that the degree of disease may be improved or aggravated by pregnancy. In some women with primary aldosteronism, the high blood levels of pregnancy-related progesterone are antagonistic at the mineralocorticoid receptor and partially block the action of aldosterone—these patients have an improvement in the manifestations of primary aldosteronism during pregnancy. In other pregnant women, increased expression of luteinizing hormone-chorionic gonadotropin receptor and gonadotropin-releasing hormone receptor have been documented in APAs and the degree of hyperaldosteronism is aggravated by the increased pregnancy-related blood levels of human chorionic gonadotropin.

The type of treatment for primary aldosteronism in pregnancy depends on how difficult it is to manage the hypertension and hypokalemia. If the patient is in the subset of patients who have a remission in the degree of primary aldosteronism, then surgery or treatment with a mineralocorticoid antagonist can be avoided until after delivery. However, if hypertension and hypokalemia are marked, then surgical and/or medical intervention is indicated. Unilateral laparoscopic adrenalectomy during the second trimester can be considered in those women with confirmed primary aldosteronism and a clear-cut unilateral adrenal macroadenoma (>10 mm).

Spironolactone crosses the placenta and is a United States Federal Drug Association (FDA) pregnancy category C drug because feminization of newborn male rats has been documented. However, there is only one human case in the medical literature where treatment with spironolactone in pregnancy led to ambiguous genitalia in a male infant—this occurred in a woman treated with spironolactone for polycystic ovarian disease pre-pregnancy and through the fifth week of gestation. Eplerenone is an FDA pregnancy category B drug. Therefore, for those pregnant women who will be managed medically, the hypertension should be treated with standard antihypertensive drugs approved for use during pregnancy. Hypokalemia, if present, should be treated with oral potassium supplements. For those patients with refractory hypertension and/or hypokalemia, the addition of eplerenone may be cautiously considered.

OTHER FORMS OF MINERALOCORTICOID EXCESS OR EFFECT

The medical disorders associated with excess mineralocorticoid effect from 11-deoxycorticosterone (DOC) and cortisol are listed in Table 10–2. These diagnoses should be considered when PAC and PRA are low in patients with hypertension and hypokalemia.

Hyperdeoxycorticosteronism

A. Congenital adrenal hyperplasia Congenital adrenal hyperplasia (CAH) is caused by enzymatic defects in adrenal steroidogenesis that result in deficient secretion of cortisol (see Chapter 14). The lack of inhibitory feedback by cortisol on the hypothalamus and pituitary produces an ACTH-driven buildup of cortisol precursors proximal to the enzymatic deficiency. A deficiency of 11β-hydroxylase (CYP11B) or 17α-hydroxylase (CYP17) causes hypertension and hypokalemia because of hypersecretion of the mineralocorticoid DOC. The mineralocorticoid effect of increased circulating levels of DOC also decreases PRA and aldosterone secretion. These defects are autosomal recessive in inheritance and typically are diagnosed in childhood. However, partial enzymatic defects have been shown to cause hypertension in adults.

a. **11β-Hydroxylase deficiency**—Approximately 5% of all cases of CAH are due to 11β-hydroxylase deficiency; the prevalence in Caucasians is 1 in 100,000. More than 40 mutations have been described in *CYP11B1*, the gene encoding 11β-hydroxylase. There is an increased prevalence among Sephardic Jews from Morocco, suggestive of a founder effect. The impaired conversion of DOC to corticosterone results in high levels of DOC, 11-deoxycortisol, and adrenal androgens (see Chapter 14). Females present in infancy or childhood with hypertension, hypokalemia, acne, hirsutism, and virilization. Males present with pseudoprecocious puberty. Approximately two-thirds of patients have mild to moderate hypertension. Markedly increased levels of DOC, 11-deoxycortisol, and adrenal androgens confirm the diagnosis. Glucocorticoid replacement normalizes the steroid abnormalities and hypertension.

b. **17α-Hydroxylase deficiency**—17α-Hydroxylase deficiency is a rare cause of CAH. 17α-Hydroxylase is essential for the synthesis of cortisol and gonadal hormones, and deficiency results in decreased production of cortisol and sex hormones. Genetic 46,XY males present with either pseudohermaphroditism or as phenotypic females, and 46,XX females present with primary amenorrhea. Therefore, a person with this form of CAH may not come to medical attention until puberty. Patients present with eunuchoid proportions and appearance. The biochemical findings include low concentrations of plasma adrenal androgens, plasma 17α-hydroxyprogesterone and cortisol. The plasma concentrations of DOC, corticosterone, and 18-hydroxycorticosterone (all produced in the zona fasciculata) are increased. Aldosterone (produced in zona glomerulosa) and PRA are suppressed. Although rare, there is an increased prevalence among Dutch Mennonites. As with 11β-hydroxylase deficiency, glucocorticoid replacement normalizes the steroid abnormalities and hypertension.

B. Deoxycorticosterone-producing tumor DOC-producing adrenal tumors are usually large and malignant. Some of them secrete androgens and estrogens in addition to DOC, which may cause virilization in women and feminization in men. A high level of plasma DOC or urinary tetrahydrodeoxycorticosterone and a large adrenal tumor seen on CT confirm the diagnosis. Aldosterone secretion in these patients is typically suppressed. Optimal treatment is complete surgical resection.

C. Primary cortisol resistance Increased cortisol secretion and plasma cortisol concentrations without evidence of Cushing syndrome are found in patients with primary cortisol resistance (or glucocorticoid resistance), a rare familial syndrome. Cortisol resistance leads to elevations in ACTH secretion which, in turn, increases adrenal steroid production. The syndrome is characterized by hypokalemic alkalosis, hypertension, increased plasma concentrations of DOC, as well as cortisol, and increased adrenal androgen secretion. The hypertension and hypokalemia are likely due to the combined effects of excess DOC and increased cortisol access to the mineralocorticoid receptor (high rates of cortisol production that overwhelm 11β-hydroxysteroid dehydrogenase type 2 [11β-HSD2] activity). Primary cortisol resistance is caused by defects in glucocorticoid receptors and assembly of the steroid–receptor complex. The treatment for the mineralocorticoid-dependent hypertension is blockade of the mineralocorticoid receptor with a mineralocorticoid receptor antagonist or suppression of ACTH secretion with dexamethasone.

Apparent Mineralocorticoid Excess Syndrome

Type 1 apparent mineralocorticoid excess (AME) is the result of impaired activity of the microsomal enzyme 11β-HSD2, which normally inactivates cortisol in the kidney by converting it to cortisone (Figure 10–9). Cortisol can be a potent mineralocorticoid, and as a result of the enzyme deficiency, high levels of
FIGURE 10–9 Interconversion of hormonally active cortisol to inactive cortisone is catalyzed by two isozymes of 11β-hydroxysteroid dehydrogenase (11β-HSD). 11β-HSD1 converts cortisone to cortisol and 11β-HSD2 inactivates cortisol to cortisone.

cortisol accumulate in the kidney. Thus, 11β-HSD2 normally excludes physiologic glucocorticoids from the nonselective mineralocorticoid receptor by converting them to the inactive 11-keto compound, cortisone. The characteristic abnormal urinary cortisol-cortisone metabolite profile seen in apparent mineralocorticoid excess reflects decreased 11β-HSD2 activity (ratio of cortisol to cortisone increased 10-fold from normal).

Decreased 11β-HSD2 activity may be hereditary or secondary to pharmacologic inhibition of enzyme activity by glycyrrhizic acid, the active principle of licorice root (*Glycyrrhiza glabra*) and some chewing tobaccos. The congenital form is a rare autosomal recessive disorder, and children present with low birth weight, failure to thrive, hypertension, polyuria and polydipsia, and poor growth. The clinical phenotype of patients with AME includes hypertension, hypokalemia, metabolic alkalosis, low PRA, low PAC, and normal plasma cortisol levels. The diagnosis is confirmed by demonstrating an abnormal ratio of cortisol to cortisone in a 24-hour urine collection. Treatment includes blockade of the mineralocorticoid receptor with a mineralocorticoid receptor antagonist or suppression of endogenous cortisol secretion with dexamethasone.

Carbenoxolone (18β-glycyrrhetinic acid sodium hemisuccinate) is a glycyrrhizic acid metabolite that is used in some countries to treat gastroesophageal reflux disorder. Carbenoxolone acts by protecting the gastrointestinal mucosal barrier from acid-pepsin attack and increasing mucosal mucin production. However, carbenoxolone is also an inhibitor of 11β-HSD2 and side effects include sodium retention, hypokalemic alkalosis, suppressed plasma renin, and hypertension.

Type 2 AME caused by ectopic ACTH secretion, seen in patients with Cushing syndrome, is related to the high rates of cortisol production that overwhelm 11β-HSD2 activity. DOC levels may also be increased in severe ACTH-dependent Cushing syndrome and contribute to the hypertension and hypokalemia in this disorder.

Liddle Syndrome—Abnormal Renal Tubular Ionic Transport

In 1963, Liddle described an autosomal dominant renal disorder that appeared to be primary aldosteronism with hypertension, hypokalemia, and inappropriate kaliuresis. However, PAC and PRA were very low in patients with Liddle syndrome; thus, another name for this disorder is "pseudoaldosteronism." Liddle syndrome is caused by mutations in the β or γ subunits of the amiloride-sensitive epithelial sodium channel—resulting in enhanced activity of the epithelial sodium channel with increased sodium reabsorption, potassium wasting, hypertension, and hypokalemia. Clinical genetic testing is available (www.genetests.org). As would be predicted, amiloride and triamterene are very effective agents to treat the hypertension and hypokalemia. However, spironolactone is ineffective in these patients. Liddle syndrome can easily be distinguished from AME based on a good clinical response to amiloride or triamterene, lack of efficacy of spironolactone and dexamethasone, and normal 24-hour urine cortisone-cortisol ratio.

Hypertension Exacerbated by Pregnancy

Hypertension exacerbated by pregnancy is a rare autosomal dominant disorder found in women with early-onset hypertension with suppressed levels of aldosterone and renin. During pregnancy, both the hypertension and hypokalemia are severely exacerbated. These patients have an activating mutation in the gene encoding the mineralocorticoid receptor which allows progesterone and other mineralocorticoid antagonists to become agonists.

OTHER ENDOCRINE DISORDERS ASSOCIATED WITH HYPERTENSION

Cushing Syndrome

Hypertension occurs in 75% to 80% of patients with Cushing syndrome (see Chapter 9). Most patients with endogenous Cushing syndrome have ACTH-dependent disease due to a corticotroph pituitary adenoma (see Table 10–2). Ectopic ACTH secretion is the second most common cause of endogenous Cushing syndrome. The ACTH-independent causes (eg, adrenal cortisol-secreting adenoma or carcinoma) of Cushing syndrome are less common. Bilateral macronodular hyperplasia (BMAH) is associated with massive nodular hyperplasia of both adrenal glands. The pathophysiology of BMAH includes paracrine production of ACTH, ectopic expression of G-protein-coupled receptors, and germline mutations in the tumor suppressor gene armadillo repeat containing 5 (*ARMC5*) (see Chapter 9). ACTH-independent primary pigmented nodular adrenal disease (PPNAD) is a bilateral form of micronodular adrenal hyperplasia that leads to Cushing syndrome. Germline mutations in *PRKAR1A* cause PPNAD in the setting of Carney complex (see Chapter 9). The mechanisms of hypertension in the setting of Cushing syndrome include increased production of DOC, enhanced pressor sensitivity to endogenous vasoconstrictors (eg, epinephrine and angiotensin II), increased cardiac output, activation of the renin-angiotensin system by increasing the hepatic production of angiotensinogen, and overload of the cortisol inactivation system with stimulation of the mineralocorticoid receptor. The source of excess glucocorticoids may be exogenous (iatrogenic) or endogenous. Mineralocorticoid production is usually normal in endogenous Cushing syndrome; aldosterone and renin levels are usually normal and DOC levels are normal or mildly increased. In patients with adrenal carcinoma, DOC and aldosterone may be elevated.

The case-detection studies for endogenous cortisol excess include: (a) measurement of free cortisol in a 24-hour urine collection; (b) midnight salivary cortisol measurement; and (c) 1-mg overnight dexamethasone suppression test. Further studies to confirm Cushing syndrome and to determine the cause of the cortisol excess state are outlined in Chapter 9.

The hypertension associated with Cushing syndrome should be treated until a surgical cure is obtained. Mineralocorticoid receptor antagonists, at dosages used to treat primary aldosteronism, are effective in reversing the hypokalemia. Second-step agents (eg, thiazide diuretics) may be added for optimal control of blood pressure.

The hypertension associated with the hypercortisolism usually resolves over several weeks after a surgical cure, and antihypertensive agents can be tapered and withdrawn.

Thyroid Dysfunction

A. Hyperthyroidism   When excessive amounts of circulating thyroid hormones interact with thyroid hormone receptors on peripheral tissues, both metabolic activity and sensitivity to circulating catecholamines increase. Thyrotoxic patients usually have tachycardia, high cardiac output, increased stroke volume, decreased peripheral vascular resistance, and increased systolic blood pressure. The initial management of patients with hypertension who have hyperthyroidism includes a β-adrenergic blocker to treat hypertension, tachycardia, and tremor. The definitive treatment of hyperthyroidism is cause specific (see Chapter 7).

B. Hypothyroidism   The frequency of hypertension, usually diastolic, is increased threefold in hypothyroid patients and may account for as much as 1% of cases of diastolic hypertension in the population. The mechanisms for the elevation in blood pressure include increased systemic vascular resistance and extracellular volume expansion. Treatment of thyroid hormone deficiency decreases blood pressure in most patients with hypertension and normalizes blood pressure in one-third of them. Synthetic levothyroxine is the treatment of choice for hypothyroidism (see Chapter 7).

Acromegaly

Chronic growth hormone (GH) excess from a GH-producing pituitary tumor results in the clinical syndrome of acromegaly. The effects of chronic excess of GH include acral and soft tissue overgrowth, progressive dental malocclusion, degenerative arthritis related to chondral and synovial tissue overgrowth within joints, low-pitched sonorous voice, excessive sweating and oily skin, perineural hypertrophy leading to nerve entrapment (eg, carpal tunnel syndrome), cardiac dysfunction, and hypertension (see Chapter 4). Hypertension occurs in 20% to 40% of the patients and is associated with sodium retention and extracellular volume expansion. Pituitary surgery is the treatment of choice; if necessary, it is supplemented with medical therapy or irradiation or both. The hypertension of acromegaly is treated most effectively by eliminating GH excess. If a surgical cure is not possible, the hypertension usually responds well to diuretic therapy.

Adrenal Medulla and Paraganglia

Paul A. Fitzgerald, MD

ACE	Angiotensin-converting enzyme		**MIBG**	Metaiodobenzylguanidine
ACTH	Adrenocorticotropic hormone		**NF-1**	Neurofibromatosis type 1
AM	Adrenomedullin		**NSE**	Neuron-specific enolase
APMO	Adnexal cystadenomas of probable mesonephric origin		**PGL**	Paraganglioma
			PHEO	Pheochromocytoma
ARDS	Acute respiratory distress syndrome		**PNMT**	Phenylethanolamine-*N*-methyltransferase
ATP	Adenosine triphosphate			
cAMP	Cyclic adenosine monophosphate		**PTHrP**	Parathyroid hormone–related peptide
CCB	Calcium channel blocker			
CgA	Chromogramin A		**RECIST**	Response evaluation criteria in solid tumors
CGRP	Calcitonin gene–related peptide			
COMT	Catecholamine-*O*-methyltransferase		**SDHA**	Succinate dehydrogenase subunit A
DBH	Dopamine-β-hydroxylase		**SDHB**	Succinate dehydrogenase subunit B
DHPG	Dihydroxyphenylglycol		**SDHC**	Succinate dehydrogenase subunit C
ECD	Electrochemical detection		**SDHD**	Succinate dehydrogenase subunit D
FDG	Fluorodeoxyglucose		**SDHx**	Succinate dehydrogenase subunits
HIF	Hypoxia-inducible factor		**SPECT**	Single photon emission computed tomography
HN-PGL	Head-neck paraganglioma			
HPLC	High-pressure liquid chromatography		**SRI**	Somatostatin receptor imaging
			VEGF	Vascular endothelial growth factor
IP₃	Inositol triphosphate		**VHL**	von Hippel-Lindau
MAO	Monoamine oxidase		**VIP**	Vasoactive intestinal polypeptide
MEN	Multiple endocrine neoplasia		**VMA**	Vanillylmandelic acid (3-methoxy-4-hydroxymandelic acid)
MHBA	3-methoxy-4-hydroxybenzylamine			

The adrenal medulla and paraganglia are part of the autonomic/sympathetic nervous system. The endocrine and nervous systems are alike in that they exert their actions by releasing hormones/neurotransmitters that bind to cell surface receptors in the target tissue, thereby inducing an effect.

Autonomic nerves are not under conscious control. They innervate the heart, adrenal medulla, vascular smooth muscle, and smooth muscle in visceral organs, thereby controlling cardiac rate and output, adrenal medullary secretion of catecholamines, blood pressure, the genitourinary tract, and intestinal motility. Autonomic nerves originate within the central nervous system and have two major divisions according to their anatomic locations:

1. **Parasympathetic** preganglionic nerves exit the central nervous system via the cranial nerves and sacral spinal nerves. They terminate in nonchromaffin paraganglia that are most numerous in the neck and associated with the glossopharyngeal and vagus nerves. These ganglia serve as chemoreceptors that are involved in the control of respiration. An important

paraganglion at the carotid bifurcation is known as the **carotid body**. They are also found along the jugular vein and in the jugulotympanic region. Head-neck paragangliomas are tumors that arise from these parasympathetic paraganglia.

2. **Sympathetic** preganglionic nerves exit the central nervous system via the thoracic and lumbar spinal nerves. The sympathetic nervous system coordinates the body's automatic *fight-flight* response by stimulating the adrenal medulla to secrete catecholamines and by directly stimulating cardiac output and blood flow to muscles while diverting blood flow away from visceral organs.

Sympathetic preganglionic nerves terminate mainly in paravertebral and prevertebral nerve ganglia where they secrete acetylcholine as their neurotransmitter; they are, therefore, known as *cholinergic* nerves. These nerve ganglia are collectively known as **paraganglia** and contain neuroendocrine cells that are similar to adrenal medullary cells on light microscopy by chromaffin and immunohistochemical staining. Paraganglia are also found in the mediastinum, particularly adjacent to the cardiac atria, and in the abdomen along the sympathetic nerve chains in paravertebral and prevertebral positions. Paraganglia are plentiful along the aorta, particularly around the celiac axis, adrenal glands, renal medullae, and aortic bifurcation (organ of Zuckerkandl). Paraganglia are also abundant in the pelvis, particularly adjacent to the bladder. Preganglionic nerves also terminate in the adrenal medulla, which is basically a sympathetic ganglion that is surrounded by adrenal cortex.

Sympathetic postganglionic nerve fibers originate from the paraganglia and run to the tissues being innervated. They secrete norepinephrine as their neurotransmitter at synaptic junctions. Adrenal medullary cells are basically modified postganglionic nerves that lack axons and secrete their neurotransmitter (mainly epinephrine) directly into the blood; thus, the bloodstream acts like a giant synapse, carrying epinephrine to receptors throughout the body. Synonyms for epinephrine and norepinephrine are *adrenalin* and *noradrenaline*, respectively (discussed later).

Although the adrenal medulla is not essential for survival, its secretion of epinephrine and other compounds helps maintain the body's homeostasis during stress. Investigations of the adrenal medulla and the sympathetic nervous system have led to the discovery of different catecholamine receptors and the production of a wide variety of sympathetic agonists and antagonists with diverse clinical applications.

Pheochromocytomas are tumors that arise from the adrenal medulla, whereas non–head-neck **paragangliomas** arise from extra-adrenal sympathetic ganglia. Pheochromocytomas can secrete excessive amounts of both epinephrine and norepinephrine, whereas most paragangliomas secrete only norepinephrine. The excessive secretion of catecholamines can result in a dangerous exaggeration of the stress response.

ANATOMY

Embryology (Figure 11–1)

The sympathetic nervous system arises in the fetus from the primitive cells of the neural crest (sympathogonia). At about the fifth
FIGURE 11–1 The embryonic development of adrenergic cells and tumors that develop from them (in parentheses). Sympathogonia are primitive cells derived from the neural crest. Neuroblasts are also called sympathoblasts; ganglion cells are the same as sympathocytes; and pheochromocytes are mature chromaffin cells.

week of gestation, these cells migrate from the spinal ganglia in the thoracic region to form the sympathetic chain posterior to the dorsal aorta. They then begin to migrate anteriorly to form the remaining ganglia.

At 6 weeks of gestation, groups of these primitive cells migrate along the central vein and enter the fetal adrenal cortex to form the adrenal medulla, which is detectable by the eighth week. The adrenal medulla at this time is composed of sympathogonia and pheochromoblasts, which then mature into pheochromocytes. The cells appear in rosette-like structures, with the more primitive cells occupying a central position. Storage granules can be found in these cells at 12 weeks. The adrenal medullas are very small and amorphous at birth but develop into recognizable adult form by the sixth month of postnatal life.

Pheochromoblasts and pheochromocytes also collect on both sides of the aorta to form the paraganglia. These cells collect principally at the origin of the mesenteric arteries and at the aortic bifurcation where they fuse anteriorly to form the organ of Zuckerkandl, which is quite prominent during the first year of life. Pheochromocytes (chromaffin cells) also are found scattered throughout the abdominal sympathetic plexi as well as in other parts of the sympathetic nervous system.

Gross Structure

The anatomic relationships between the adrenal medulla and the adrenal cortex differ in different species. In mammals, the medulla is surrounded by the adrenal cortex, and in humans, the adrenal medulla occupies a central position in the widest part of the gland, with only small portions extending into the narrower parts. The mass of adrenal medullary tissue in both adult adrenal glands averages about 1000 mg (about 15% of the total weight of both adrenal glands), although the proportions vary from individual to individual. There is no clear demarcation between cortex and medulla. A cuff of adrenal cortical cells usually surrounds the central vein within the adrenal medulla, and there may be islands of cortical cells elsewhere in the medulla.

Microscopic Structure

The **chromaffin cells** or **pheochromocytes** of the adrenal medulla are large ovoid columnar cells arranged in nests, alveoli, or cords around a rich network of capillaries and venous sinusoids that drain blood from the adrenal cortex. Pheochromocytes have large nuclei and a well-developed Golgi apparatus. Their cytoplasm contains large numbers of vesicles (granules) that measure 100 to 300 nm in diameter and appear similar to the neurosecretory granules seen in peripheral sympathetic nerves. Catecholamines (epinephrine and/or norepinephrine) comprise about 20% of the mass of neurosecretory vesicles. Vesicles containing norepinephrine appear darker than those containing epinephrine. The vesicles also contain proteins, lipids, and adenosine triphosphate (ATP), as well as chromogranins, neuropeptide Y, enkephalins, and proopiomelanocortin (along with related peptides such as adrenocorticotropic hormone [ACTH] and β-endorphin).

Nerve Supply

The cells of the adrenal medulla are innervated by preganglionic fibers of the sympathetic nervous system, which release acetylcholine and enkephalins at the synapses. Most of these fibers arise from a plexus in the capsule of the posterior surface of the gland and enter the adrenal glands in bundles of 30 to 50 fibers without synapsing. They follow the course of the blood vessels into the medulla without branching into the adrenal cortex. Some reach the wall of the central vein, where they synapse with small autonomic ganglia. However, most fibers end in relationship to the pheochromocytes.

Blood Supply

The adrenal gland is usually perfused by the superior, middle, and inferior adrenal branches of the inferior phrenic artery, directly from the aorta and from the renal arteries. On reaching the adrenal gland, these arteries branch to form a plexus under the capsule supplying the adrenal cortex. A few of these vessels, however, penetrate the cortex, passing directly to the medulla. The medulla is also nourished by branches of the arteries supplying the central vein and cuff of cortical tissue around the central vein. Capillary loops passing from the subcapsular plexus of the cortex also supply blood as they drain into the central vein. Most of the blood supply to adrenal medullary cells is via a portal vascular system that arises from the capillaries in the cortex. There is also a capillary network of lymphatics that drain into a plexus around the central vein.

Norepinephrine is converted to epinephrine by the enzyme phenylethanolamine-*N*-methyltransferase (PNMT). In mammals, the expression of PNMT is induced by cortisol. Chromaffin cells that produce epinephrine are exposed to higher concentrations of cortisol from capillaries draining adrenocortical cells, whereas chromaffin cells that produce norepinephrine are supplied by arteries that course directly to the adrenal medulla (see sections on biosynthesis and secretion, discussed later).

The central vein of the right adrenal is short and drains directly into the vena cava with about 5% having multiple veins. About 5% of right adrenal veins drain into the hepatic vein. For the left adrenal gland, the vein is somewhat longer and drains into the left renal vein.

HORMONES OF THE ADRENAL MEDULLA AND PARAGANGLIA

CATECHOLAMINES

Biosynthesis (Figure 11–2)

Catecholamines are molecules that have a catechol nucleus consisting of benzene with two hydroxyl side groups plus a side-chain amine. Catecholamines include dopamine, norepinephrine, and epinephrine (see Figure 11–2).

Epinephrine is the main hormone secreted by the normal adrenal medulla. The proportions of epinephrine and norepinephrine
FIGURE 11–2 Biosynthesis of catecholamines (DOPA: L-dihydroxyphenylalanine; PNMT: phenylethanolamine-*N*-methyltransferase). Epinephrine is not produced in paraganglia.

found in the adrenal medulla vary with the species; in humans, the adrenal medulla contains 15% to 20% norepinephrine.

Norepinephrine is found primarily in the central nervous system and in peripheral sympathetic paraganglia and nerves. Dopamine is found in the adrenal medulla and in sympathetic neurons as a precursor to norepinephrine. It is present in high concentrations in the brain, in specialized neurons in the sympathetic ganglia, and in the carotid body, where it serves as a neurotransmitter. Dopamine is also present in the proximal renal tubule where it promotes sodium excretion and in the gastrointestinal tract where it serves a paracrine function.

Chromogranin A (CgA) is a peptide that is stored and released with catecholamines during exocytosis; catestatin is a fragment of the CgA prohormone that inhibits further catecholamine release by acting as an antagonist at the neuronal cholinergic receptor. CgA levels tend to be somewhat higher in patients with hypertension than in matched normotensive individuals. CgA has become a valuable tumor marker, particularly for patients with paragangliomas that are otherwise nonsecretory.

A. Conversion of tyrosine to DOPA   Tyrosine is the precursor to all catecholamines. Tyrosine is derived from ingested food and synthesized from phenylalanine in the liver. Tyrosine circulates at a concentration of 1 to 1.5 mg/dL of blood. It enters neurons and chromaffin cells by an active transport mechanism and is converted to L-3,4-dihydroxyphenylalanine (L-DOPA). Humans produce only the levo isomer, so L-DOPA is also referred to as simply DOPA. The reaction is catalyzed by *tyrosine hydroxylase*, which is transported via axonal flow to the nerve terminal. Tyrosine hydroxylase is the rate-limiting step in catecholamine synthesis. It is transcriptionally activated by acetylcholine through the nicotinic cholinergic receptor, which in turn activates protein kinase A via cAMP. Tyrosine hydroxylase activity may be inhibited by a variety of compounds; alpha methyltyrosine (metyrosine) is an inhibitor that may be used to reduce catecholamine secretion in patients with pheochromocytoma or paraganglioma.

B. Conversion of DOPA to dopamine   DOPA is converted to dopamine by the removal of its carboxyl group by the enzyme aromatic L-amino acid decarboxylase (DOPA decarboxylase). This enzyme is found in all tissues, with the highest concentrations in liver, kidney, vas deferens, and brain. In the brain, dopamine functions as an important neurotransmitter.

C. Conversion of dopamine to norepinephrine   Dopamine enters granulated storage vesicles where it is hydroxylated to norepinephrine by the enzyme dopamine-β-hydroxylase (DBH), which is found within the vesicle membrane. Norepinephrine is then actively transported into the vesicle by vesicular monoamine transferase (VMAT), which is located in the lipid bilayer of the vesicle wall. Norepinephrine constantly diffuses out of the vesicle, so it is best to consider it being concentrated in the vesicle, rather than being stored there. The granulated storage vesicle migrates to the cell surface and secretes its contents via exocytosis; both norepinephrine and DBH are released during exocytosis. After

secretion, most norepinephrine is avidly recycled back into the nerve. Normally, about 93% of circulating norepinephrine originates from diffusion out of nonadrenal sympathetic nerve cells and synapses, while only 7% originates from the adrenal medulla.

D. Conversion of norepinephrine to epinephrine   Norepinephrine constantly diffuses out from storage granules into the cytoplasm. In most cells of the adrenal medulla, cytoplasmic norepinephrine is converted to epinephrine, catalyzed by PNMT. Epinephrine can then return to the vesicle, diffuse from the cell, or undergo catabolism. High concentrations of cortisol enhance the expression of the gene encoding PNMT. Cortisol is present in high concentrations in most areas of the adrenal medulla due to venous blood flow from the adjacent adrenal cortex. This accounts for the fact that in the normal human adrenal medulla, about 80% of the catecholamine content is epinephrine and only 20% is norepinephrine. The administration of exogenous corticosteroids increases adrenal medullary PNMT expression, despite suppression of ACTH and endogenous adrenal cortisol production

Paragangliomas rarely secrete epinephrine, because they do not have high local concentrations of cortisol to induce PNMT expression. Pheochromocytomas secrete epinephrine and norepinephrine in various ratios. Interestingly, after adrenalectomy, recurrent pheochromocytoma can secrete epinephrine without any surrounding adrenal cortex, indicating that the induction of PNMT may continue in subsequent metastatic cell lineages without high local levels of cortisol. After both adrenal glands are resected, serum epinephrine levels abruptly fall to nearly zero, whereas norepinephrine concentrations decline minimally, since most circulating norepinephrine originates from leakage out of sympathetic nerves and synapses.

The enzyme PNMT is found in many tissues outside the adrenal medulla. PNMT has been found in the lungs, kidneys, pancreas, and cancer cells. Therefore, nonadrenal tissue is capable of synthesizing epinephrine if norepinephrine is available as a substrate. However, nonadrenal production of epinephrine usually contributes minimally to circulating levels. PNMT is found in human lung, and glucocorticoids increase its expression, thereby increasing lung epinephrine. This may possibly contribute to the bronchial dilation that is induced by glucocorticoids (inhaled or systemic). PNMT activity is also found in red blood cells, where its activity is increased in hyperthyroidism and decreased in hypothyroidism. Renal PNMT activity is such that normally up to one-half of the epinephrine found in normal urine may be the product of renal conversion from norepinephrine.

In the adrenal medulla, catecholamine stores can be depleted during prolonged hypoglycemia. Biosynthesis of catecholamines increases during nerve stimulation by activation of tyrosine hydroxylase. Prolonged stimulation leads to the induction of increased amounts of this rate-limiting enzyme.

Storage of Catecholamines

Catecholamines are not truly stored in intracellular vesicles. Rather, they exist in a dynamic equilibrium between the vesicle

and the surrounding cytoplasm. Catecholamines continuously leak out of the vesicles into the cytoplasm but reenter and become concentrated in the vesicles by the action of two vesicular mono-amine transporters: VMAT-1 and VMAT-2. Both are expressed in the adrenal medulla, but only VMAT-2 is expressed in sympathetic nerves.

In the adrenal medulla, the percentage of stored epinephrine (vs total catecholamines) varies widely among different species. In the human adrenal medulla, epinephrine comprises about 80% of stored catecholamines. Epinephrine and norepinephrine are stored in different cells. Morphologic differences in epinephrine and norepinephrine storage vesicles are visible on light microscopy after proper staining. Cells that store predominantly epinephrine tend to be adjacent to intramedullary sinusoidal vessels that bathe the cells in blood from the adrenal cortex; such blood contains cortisol that induces the enzyme PNMT that catalyzes the conversion of norepinephrine to epinephrine in the cytoplasm such that these vesicles contain predominantly epinephrine. Adrenal medullary cells that contain predominantly norepinephrine tend to be farther away from such vessels.

Norepinephrine is the neurotransmitter that is secreted at the synapses of postganglionic sympathetic nerves in organs that have rich autonomic innervations: the heart, salivary glands, vascular smooth muscle, liver, spleen, kidneys, and muscles. A single sympathetic nerve cell may have up to 25,000 synaptic bulges along the length of its axon; each synapse synthesizes norepinephrine and stores it in adrenergic synaptic vesicles adjacent to target cells.

Catecholamine biosynthesis is coupled to secretion, so that the stores of norepinephrine at the nerve endings remain relatively unchanged even in the presence of marked nerve activity. The adrenal medulla contains catecholamines at a concentration of about 0.5 mg/g; the spleen, vas deferens, brain, spinal cord, and heart contain 1 to 5 μg/g; and the liver, gut, and skeletal muscle contain 0.1 to 0.5 μg/g. Catecholamines are stored in electron-dense vesicles approximately 1 μm in diameter that contain catecholamines and ATP in a 4:1 molar ratio, as well as several neuropeptides, calcium, magnesium, and water-soluble proteins called **chromogranins** (discussed earlier). The interior surface of the membrane contains DBH and ATPase. The Mg^{2+}-dependent ATPase facilitates the uptake and inhibits the release of catecholamines by the granules. Adrenal medullary granules appear to contain and release a number of active peptides including adrenomedullin, ACTH, vasoactive intestinal peptide (VIP), chromogranins, and enkephalins. The peptides derived from chromogranins are physiologically active and may modulate catecholamine release.

Secretion of Catecholamines (Figure 11–3 and Table 11–1)

Preganglionic nerve fibers terminate at adrenal medullary cells, where they release acetylcholine at synapses and stimulate adrenal medullary receptors. Activation of the receptors depolarizes the cell membranes and causes an influx of calcium ions. The increased intracellular concentration of calcium triggers exocytosis of the neurosecretory vesicles with consequent release of their contents:

catecholamines, chromogranins, and soluble DBH. Vesicular membrane-bound DBH is not released during exocytosis.

Adrenal medulla.   In the adrenal medulla, exocytosis of the neurosecretory vesicles releases epinephrine and norepinephrine into the circulation. In normals, about 95% of circulating epinephrine is derived from the adrenal medulla, whereas adrenal medullary secretion accounts for only about 7% of circulating norepinephrine. Catecholamines also diffuse out of the neurosecretory vesicles into the cytoplasm. Catecholamines in the cytoplasm may reenter a vesicle via VMAT or may be metabolized by COMT into catecholamine metabolites: metanephrine and normetanephrine, which gradually diffuse out of the cell and enter the circulation.

Adrenal medullary catecholamine secretion increases with exercise, angina pectoris, myocardial infarction, hemorrhage, ether anesthesia, surgery, hypoglycemia, anoxia and asphyxia, and many other stressful stimuli. The rate of secretion of epinephrine increases more than that of norepinephrine in the presence of hypoglycemia and most other stimuli. However, during hypoxia, the adrenal medullary cells preferentially release norepinephrine. Such release is mainly not by exocytosis but rather by leakage of norepinephrine from neurosecretory vesicles into the cytoplasm and out of the cell into the circulation. The preferential release of norepinephrine may be because the adrenal medullary cells that concentrate norepinephrine are located farther from blood vessels and may be more susceptible to hypoxic injury (see Storage of Catecholamines, discussed earlier).

Sympathetic neurons.   In sympathetic neurons, exocytosis of the neurosecretory vesicle releases norepinephrine into the synapse by exocytosis. Norepinephrine that has been secreted into a synapse is either reabsorbed via norepinephrine transporters (NETs) or leaks out of the synapse into the circulation. Such synaptic leakage accounts for about 93% of circulating norepinephrine in normal individuals.

Metabolism and Excretion of Catecholamines (Figures 11–4 and 11–5)

A. Catecholamine metabolism in cells of origin

Adrenal medulla.   In the adrenal medulla, catecholamines are metabolized to metanephrines primarily by membrane-bound catecholamine-*O*-methyltransferase (COMT): epinephrine to metanephrine and norepinephrine to normetanephrine. The metanephrine metabolites subsequently leak into the circulation. Normally, about 91% of circulating metanephrine is produced by the adrenal medulla, while the remaining 9% is derived from the metabolism of circulating epinephrine to metanephrine by the enzyme COMT found in the liver and other non-adrenal tissues. Similarly, in normals, about 23% of circulating normetanephrine is produced by the adrenal medulla, while 77% is derived from the metabolism of circulating norepinephrine to normetanephrine by the enzyme COMT found in the liver and other non-adrenal tissues (see Figure 11–5).
FIGURE 11–3 Schematic diagram of a noradrenergic junction of the peripheral sympathetic nervous system (not to scale). The neural axons form synaptic junctions with cells in target organs. The neurotransmitter is norepinephrine that has been either synthesized de novo from tyrosine or reabsorbed by a norepinephrine transporter (NET). Tyrosine is transported into the noradrenergic endings or varicosities by a sodium-dependent carrier (A). In the cytoplasm, tyrosine hydroxylase converts tyrosine to DOPA that is converted by DOPA decarboxylase to dopamine. Dopamine, as well as norepinephrine (NE) is transported into the vesicles by vesicular monoamine transferase (VMAT). Dopamine is converted to NE in the vesicle by DBH. Exocytosis of the neurosecretory vesicle with release of transmitter occurs when an action potential opens voltage-sensitive calcium channels and increases intracellular calcium. Fusion of vesicles with the surface membrane results in expulsion of norepinephrine, cotransmitters, and DBH. After release, norepinephrine diffuses out of the cleft or is transported into the cytoplasm of the nerve itself (uptake 1) or transported into the postjunctional target cell (uptake 2). Regulatory receptors are present on the presynaptic terminal (SNAPs, synaptosome-associated proteins; VAMPs, vesicle-associated membrane protein). **Not shown:** In adrenal medullary and pheochromocytoma cells, norepinephrine constantly diffuses from the vesicle into the cytoplasm where it may be converted to epinephrine by phenylethanolamine-*N*-methyltransferase (PNMT). Alternatively, cytoplasmic membrane-bound catecholamine-*O*-methyltransferase (COMT) can metabolize epinephrine and norepinephrine directly into metanephrine and normetanephrine, respectively, which are then released. (Reproduced with permission from Katzung BJ. *Basic & Clinical Pharmacology*. 11th ed. New York: McGraw-Hill Education; 2009.)

TABLE 11–1 Range of plasma catecholamine levels observed in healthy subjects and patients without pheochromocytoma or paraganglioma.

	Norepinephrine	Epinephrine
Healthy Subjects		
Basal (supine)	112-658 pg/mL (0.7-3.9 nmol/L)	25-50 pg/mL (0.1-0.3 nmol/L)
Ambulatory	217-1109 pg/mL (1.3-6.5 nmol/L)	30-95 pg/mL (0.2-0.5 nmol/L)
Exercise	800-4000 pg/mL (4.7-23.6 nmol/L)	100-1000 pg/mL (0.5-5 nmol/L)
Symptomatic hypoglycemia	200-1000 pg/mL (1.2-5.9 nmol/L)	1000-5000 pg/mL (5-25 nmol/L)
Patients		
Hypertension	200-500 pg/mL (1.2-3 nmol/L)	20-100 pg/mL (0.1-0.6 nmol/L)
Surgery	500-2000 pg/mL (3-12 nmol/L)	199-500 pg/mL (0.5-3 nmol/L)
Myocardial infarction	1000-2000 pg/mL (6-12 nmol/L)	800-5000 pg/mL (4-25 nmol/L)

Sympathetic nerves. Catecholamines that are released at the synapse bind to their receptors with relatively low affinity and dissociate rapidly (see Figure 11–4). About 10% of norepinephrine escapes from synapses into the systemic circulation (discussed later). About 90% of synaptic norepinephrine is reabsorbed by the nerves from which they were released or by the target cells.

Cytoplasmic norepinephrine is metabolized to 3,4-dihydroxyphenylglycol (DHPG) at the outer mitochondrial membrane by the enzyme monoamine oxidase (MAO) that regulates the norepinephrine content of neurons. Sympathetic nerves do not contain the enzyme COMT. DHPG leaks from the neuron and is absorbed by the liver and other tissues that contain the enzyme COMT that converts DHPG to 3-methoxy-4-hydroxyphenylglycol (MHPG), with subsequent conversion to vanillylmandelic acid (VMA) (discussed later) that is excreted in the urine. In normals, most urinary VMA is derived from DHPG that leaks from sympathetic nerves.

Sympathetic nerves in abdominal organs, particularly the intestines and pancreas, account for nearly half the body's production of norepinephrine. Intestinal cells contain sulfatases that conjugate norepinephrine to norepinephrine-SO_4 that enters the portal vein and bypasses the liver to be excreted in the urine. Intestinal cells also conjugate normetanephrine to normetanephrine-SO_4.

Pheochromocytomas. In pheochromocytomas (PHEOs), catecholamines that leak out of the neurosecretory vesicles are methylated by membrane-bound COMT: epinephrine to metanephrine and norepinephrine to normetanephrine. These metanephrine metabolites continuously leak directly into the circulation, in contrast to catecholamines that are secreted intermittently. The PHEO/PGL's continuous excretion of metanephrines accounts for the superior sensitivity of plasma or urine-fractionated free metanephrine testing in the diagnosis of
FIGURE 11–4 Metabolism of catecholamines by catechol-*O*-methyltransferase (COMT), monoamine oxidase (MAO), aldehyde dehydrogenase (AD), and phenol-sulfotransferase (PST). (1) Adrenal medulla or PHEO; (2) sympathetic nerves; (3) liver and kidneys; (4) GI, platelets, lungs.
FIGURE 11–5 Location of catecholamine metabolism by normal adrenal medullary cells, sympathetic nerve cells, and extraneuronal cells (liver, kidneys) and their relative contributions to plasma levels. Most metabolism of norepinephrine (NE) in sympathetic nerves occurs from NE that has leaked from storage vesicles and undergoes deamination, in the sympathoneuronal cytoplasm that is catalyzed by monoamine oxidase (MAO) to form DHPG that leaks into the circulation. Similarly, in adrenal medullary chromaffin cells and chromaffin tumors (PHEO and PGL), metabolism occurs within cells from NE and epinephrine (E) leaking from storage vesicles into the cytoplasm, where the presence of catechol-amine-*O*-methyltransferase (COMT) leads to formation of normetanephrine (NMN) and metanephrine (MN), respectively, which leak into the circulation. COMT is not present in sympathetic nerves, but it is present in extraneuronal cells (liver, kidney), where it metabolizes DHPG to MHPG, the main precursor of vanilyl mandelic acid (VMA) that is excreted in the urine. The COMT in extraneuronal tissues is also responsible for production of a small proportion of circulating MN (9%), derived from E metabolized after release from chromaffin cells, as well as a larger proportion of circulating NMN (77%) derived mainly from NE released by sympathetic nerves. (Reproduced with permission from Eisenhofer G, Peitzsch M. Laboratory evaluation of pheochromocytoma and paraganglioma. *Clin Chem*. 2014 Dec;60(12):1486-1499.)

PHEO. In patients with PHEO, over 90% of circulating total metanephrines are derived from the tumor itself, rather than from peripheral metabolism.

B. Circulating catecholamine uptake and metabolism

Following release into the circulation, catecholamines bind to albumin and other proteins with low affinity and high capacity. Catecholamines are quickly removed from the bloodstream and have a circulating half-life of less than 2 minutes. Although some free catecholamines are excreted directly into the urine, most are actively transported from the circulation into other cells where they are metabolized. Organic cation transporters (OCTs) are largely responsible for removing catecholamines from the circulation; they are expressed in many tissues, particularly the liver. Following active transport into a cell, catecholamines and their immediate metabolites undergo further metabolism. The main extra-adrenal/neuronal catecholamine metabolic pathway is initially via the enzyme MAO that converts both epinephrine and norepinephrine to DHPG. DHPG is further metabolized by soluble COMT to MHPG that is converted by aldehyde dehydrogenase (AD) to VMA that is excreted in the urine.

Catecholamines, metanephrines, and MHPG also undergo conjugation of their phenolic hydroxyl group with sulfate or glucuronide; this reaction occurs mainly in gastrointestinal cells. To a lesser extent, catecholamines are also converted to metanephrines via a soluble form of COMT, an enzyme found in most tissues, especially blood cells, liver, kidney, and vascular smooth muscle.

The soluble form of COMT is less active than the membrane-bound form of COMT found in the adrenal medulla and pheochromocytomas.

Catecholamines, their metabolites, and conjugates are excreted in the urine. Normally, the proportions of urine catecholamines and metabolites are approximately 50% metanephrines, 35% VMA, 10% conjugated catecholamines and other metabolites, and less than 5% free catecholamines.

CATECHOLAMINE (ADRENERGIC) RECEPTORS (TABLES 11–2 AND 11–3; FIGURES 11–6 AND 11–7)

The adrenergic receptors are G protein–coupled receptors activated by norepinephrine and epinephrine. The finding that most cells in the body have adrenergic receptors has led to an appreciation of the important regulatory role of the peripheral sympathetic nervous system and circulating catecholamines.

Adrenergic receptors were originally classified into two groups: α and β. This classification has been expanded as subtypes of the α and β receptors have been discovered and includes α_{1A}, α_{1B}, α_{1C}, α_{2A}, α_{2B}, α_{2C} as well as β_1 and β_2, and β_3. There are five known dopamine receptor subtypes that are classified as either delta-1 type receptors or delta-2 type receptors. A different gene encodes each receptor subtype. Adrenergic receptors are variably distributed in the central nervous system and peripheral tissues.

TABLE 11–2 Catecholamine receptor types, subtypes, and cellular effects.

Receptor	Relative Agonist Potency	Effects
Alpha₁ Type Alpha$_{1A}$ Alpha$_{1B}$ Alpha$_{1D}$	Norepinephrine > epinephrine; midodrine	↑ IP$_3$, DAG common to all
Alpha₂ Type Alpha$_{2A}$	Norepinephrine > epinephrine; clonidine	↓ cAMP; ↑K$^+$ channels; ↓ Ca^{2+} channels
Alpha$_{2B}$	Norepinephrine > epinephrine	↓ cAMP; ↓Ca^{2+} channels
Alpha$_{2C}$		↓ cAMP
Beta Type Beta$_1$	Epinephrine = norepinephrine; dobutamine	↑ cAMP
Beta$_2$	Epinephrine > norepinephrine; albuterol	↑ cAMP
Beta$_3$	Norepinephrine > epinephrine	↑ cAMP
Delta-1 Type D$_1$ & D$_5$	Dopamine	↑ cAMP
Delta-2 Type D$_2$ & D$_3$ & D$_4$	Dopamine, bromocriptine, cabergoline	↓ cAMP

Data from Katzung BJ. *Basic & Clinical Pharmacology*. 13th ed. New York: McGraw-Hill Education; 2015.

Norepinephrine and epinephrine are roughly equipotent in activating α and β₁ receptors. Epinephrine is much more potent in activating β₂ receptors and norepinephrine is more potent in activating β₃ receptors (Table 11–2). The physiologic effects mediated by them are summarized in Table 11–3.

Although the adrenergic receptor subtypes exhibit significant amino acid homology, differences in the fifth and sixth segments determine the specificity of agonist binding. Differences in the fifth and seventh segments determine which of the guanylyl nucleotide binding proteins (G proteins) is coupled to the receptor. G proteins consist of α, β, and γ subunits. When a hormone binds to the receptor, the β and γ subunits dissociate from the α subunit, allowing GDP to be replaced by GTP on the α subunits and causing the β and γ subunits to dissociate from it. The GTP-bound α subunits activate phospholipase C, leading to the release of stored calcium that activates Ca^{2+}-dependent protein kinase (see Figure 11–6).

A. Alpha-adrenergic receptors   Alpha₁ receptors are G$_q$-coupled receptors with three homologous subtypes: α$_{1A}$, α$_{1B}$, and α$_{1C}$. When an agonist binds to the α₁ receptor, the alpha subunit of the guanylyl nucleotide-binding protein, G$_q$, is released and activates phospholipase C. This enzyme catalyzes the conversion of phosphatidylinositol 4,5-bisphosphate to 1,4,5-inositol triphosphate (IP$_3$) and diacylglycerol. IP$_3$ releases calcium ion from intracellular stores to stimulate physiologic responses. Diacylglycerol activates protein kinase C, which in turn phosphorylates a

series of other proteins that initiate or sustain effects stimulated by the release of IP$_3$ and calcium ion (see Figure 11–6). Prazosin and phenoxybenzamine are selective antagonists of the α₁ receptor.

Alpha₁ receptors are postsynaptic (target organ) receptors that mediate diverse effects, particularly arteriolar vasoconstriction. Hepatic α₁ receptors stimulate glycogenolysis and gluconeogenesis. In the eye, α₁ receptors stimulate contraction of the radial muscle of the iris that dilates the pupil. In the skin, α₁ receptors mediate apocrine sweating and pilomotor contraction. In the genitourinary tract, α₁ receptors mediate ejaculation, gravid uterine contraction, and contraction of the bladder sphincter and trigone. In the intestines, α₁ receptors reduce smooth muscle contraction and increase sphincter tone, thereby promoting constipation. Alpha₁ receptors are also found in the splenic capsule and mediate the contraction of the capsule (particularly during hypoxia), which contracts the splenic volume up to 20% and can expel up to 125 mL of packed red blood cells into the circulation within 3 seconds of apnea.

Sympathetic nerves secrete norepinephrine into synaptic junctions where the concentration of norepinephrine is high, thereby stimulating synaptic effector organ α₁ receptors. Epinephrine has a similar effect upon α₁ receptors but is secreted only by the adrenal medulla such that circulating concentrations are usually much lower than concentrations of synaptic norepinephrine. At low plasma concentrations, epinephrine predominantly stimulates β₂-adrenergic receptors (causing vasodilation, discussed later), whereas at higher plasma concentrations, epinephrine stimulates α₁ receptors sufficiently to override vasodilation and cause vasoconstriction.

Alpha₂ receptors are G$_i$ coupled receptors with three highly homologous subtypes: α$_{2A}$, α$_{2B}$, and α$_{2C}$. Agonist binding to the α₂ receptor releases G$_i$ alpha, which inhibits the enzyme adenylyl cyclase and reduces the formation of cAMP (Figure 11–7).

Presynaptic (nerve) α₂ receptors are located near the synapses of sympathetic nerves. Synaptic norepinephrine binds to this receptor, resulting in feedback inhibition of its own release. Alpha₂ receptors are also found in vascular smooth muscle where they mediate vasoconstriction. Alpha₂ receptors in platelets stimulate platelet aggregation and clotting. In the brain, α₂ receptors are found in the locus ceruleus, cerebral cortex, and limbic system. Although their location is postsynaptic, stimulation of the α₂ receptors results in reduced release of norepinephrine. Clonidine is a central α₂ agonist. Yohimbine is a selective antagonist for the α₂ receptor. Phentolamine is an antagonist for both α₁ and α₂ receptors.

In the pancreatic beta cells, activation of α₂ receptors inhibits insulin secretion. This causes glucose intolerance in patients with pheochromocytoma. The gene *Adra2a* encodes the adrenergic α$_{2A}$ receptor. A polymorphism in *Adra2a* increases the number of α$_{2A}$ receptors on beta cells, which reduces insulin secretion and increases the risk of type 2 diabetes mellitus.

B. Beta-adrenergic receptors   Beta-adrenergic receptors are postsynaptic (target organ) cell surface glycoproteins. Agonist binding to β-adrenergic receptors activates adenylyl cyclase via the G$_s$ alpha subunit to increase the production of cAMP, which in

TABLE 11–3 Catecholamine receptors: location and clinical effects following receptor activation.

Catecholamine Receptor	Tissue Location	Clinical Effects Following Receptor Activation
Alpha$_1$	Vascular smooth muscle Liver Eye Skin Prostate Uterus Intestines Spleen capsule	Increases vasoconstriction (increases blood pressure) Increases glycogenolysis and gluconeogenesis Increases ciliary muscle contraction (pupil dilation) Increases pilomotor smooth muscle contraction (erects hairs) Increases contraction and ejaculation Increases gravid uterus contraction Increases sphincter tone and relaxes smooth muscle Contracts spleen volume, expelling blood
Alpha$_2$	Preganglionic nerves Vascular smooth muscle Pancreatic islet cells Blood platelets Adipose cells Brain	Decreases release of neurotransmitter Increases vasoconstriction (increases blood pressure) Decreases release of insulin and glucagon Increases platelet aggregation Decreases lipolysis Decreases norepinephrine release
Beta$_1$	Myocardium Kidney (juxtaglomerular apparatus) Adipose cells Most tissues Nerves	Increases force and rate of contraction Increases secretion of renin Increases lipolysis Increases calorigenesis Increases conduction velocity
Beta$_2$	Vascular smooth muscle Bronchiolar smooth muscle Liver Intestinal smooth muscle Pancreatic islet cells Adipose tissue Muscles Liver and kidney Uterus smooth muscle	Decreases vasoconstriction (increases blood flow) Decreases contraction (bronchial dilation) Increases glycogenolysis and gluconeogenesis Decreases intestinal motility; increases sphincter tone Increases release of insulin and glucagon Increases lipolysis Increases muscle contraction speed and glycogenolysis Increases peripheral conversion of T_4 to T_3 Decreases nongravid uterine contraction (uterine relaxation)
Beta$_3$	Adipose cells Intestinal smooth muscle	Increases lipolysis Increases intestinal motility
Dopamine$_1$	Vascular smooth muscle Renal tubule	Decreases vasoconstriction (vasodilation) Enhances natriuresis
Dopamine$_2$	Sympathetic nerves Pituitary lactotrophs Gastrointestinal tract Brain	Inhibits synaptic release of norepinephrine Inhibits prolactin release Paracrine functions Neurotransmitter

turn converts protein kinase A to its active form. Protein kinase A then phosphorylates a variety of proteins, including enzymes, ion channels, and receptors (see Figure 11–7).

Beta$_1$-adrenergic receptors are located primarily in the heart, kidneys, and adipose tissue. In the heart, β_1 receptors are located in the sinoatrial (SA) and atrioventricular (AV) nodes, atrium, ventricle, and conduction system; activation of these receptors mediates an increase in heart rate and cardiac contraction with an overall increase in cardiac output. Stimulation of β_1 receptors in the ventricles also increases the firing of idioventricular pacemakers such that excessive stimulation predisposes to ventricular ectopy. Triiodothyronine (T_3) increases the total number of cardiac β_1 receptors; this may contribute to the forceful cardiac contraction and tachyarrhythmias that are characteristic of hyperthyroidism. Beta$_1$ receptors in the renal juxtaglomerular apparatus stimulate the release of renin that, in turn, activates the renin-angiotensin system. In fat cells, activation of β_1 receptors increases lipolysis. In nerve cells, activation of β_1 receptors increases nerve conduction velocity. In the brain, β_1 receptors are

found particularly in the nucleus accumbens and the ventral putamen (striatum).

Beta$_2$-adrenergic receptors are particularly activated by epinephrine. They are located mainly in the smooth muscles of arterioles, veins, and bronchi where they mediate relaxation. In the heart, β_2 receptors are located in the same locations as β_1 receptors (discussed earlier) and likewise mediate increases in cardiac rate and contraction. β_2 Receptors are also located in smaller coronary arteries where they mediate dilation of the coronaries, thereby increasing blood flow to cardiac muscle. Vascular β_2 receptors mediate vasodilation of arterioles, particularly in skeletal muscle and the hepatic artery. Stimulation of venous β_2 receptors mediates venous dilation. Stimulation of β_2 receptors also causes relaxation of other smooth muscles, resulting in bronchial dilation and relaxation of the nonpregnant uterus. During exercise or hypoglycemia, epinephrine is secreted and activates hepatic β_2 receptors. This stimulates glycogenolysis and gluconeogenesis for the increased glucose production that is needed for increased cardiac and skeletal muscle activity. Beta$_2$ receptors in skeletal muscle
FIGURE 11–6 Activation of α_1-adrenergic responses. Stimulation of α_1 receptors by catecholamines leads to the activation of a G_q-coupling protein. The activated α_q subunit (α_q^*) of this G protein activates phospholipase C, which catalyzes the conversion of PtdIns 4,5-P_2 (phosphatidylinositol 4,5-bisphosphate) to IP_3 (inositol 1,4,5-trisphosphate) and DAG (diacylglycerol). IP_3 stimulates the release of sequestered stores of calcium, leading to an increased concentration of cytoplasmic Ca^{2+} that may then activate Ca^{2+}-dependent protein kinases that phosphorylate their substrates. DAG activates protein kinase C (PKC) (GDP, guanosine diphosphate; GTP, guanosine triphosphate). See Table 11–3 and text for physiologic effects of α_1 receptor activation. (Reproduced with permission from Katzung BJ. *Basic & Clinical Pharmacology*. 12th ed. New York: McGraw-Hill Education; 2012.)

promote increased contraction speed, glycogenolysis, and tremor. The net effect of β_2 agonists (eg, epinephrine) upon liver and skeletal muscle is to increase serum glucose. Beta$_2$-adrenergic receptors are also expressed in various areas of the brain, particularly the right hippocampus, which normally has a higher density of β_2 receptors than the left hippocampus.

Beta$_3$-adrenergic receptors are expressed mainly in adipose tissue but also in the gallbladder, colon, central nervous system, and heart. Activation of this receptor increases energy expenditure, lipolysis, and intestinal motility. β_3 Receptor activation promotes lipolysis in adipose tissue and increased thermogenesis in skeletal muscle. Although β_3-adrenergic receptors are found in the brains of infants, by adulthood their concentration decreases by 100-fold. Pima Indians, who are homozygous for inactivating mutations in the β_3 gene, have an earlier onset of type 2 diabetes.

C. Dopamine receptors   Five different dopamine receptors have been identified (D_1 to D_5), each encoded by a different gene. Dopamine receptors are found throughout the brain (including the anterior pituitary), arteries, proximal renal tubules, and gastrointestinal tract. D_1 and D_2 receptors are the predominant subtypes.

D_1-like family of receptors (D_1 and D_5) couples to G_s that activates adenyl cyclase, thereby increasing intracellular cyclic AMP (cAMP). D_1 receptors mediate vasodilation in the coronary,

renal, cerebrovascular, and mesenteric arteries. D_1 receptors in the proximal renal tubule enhance natriuresis. The D_1 receptor is the most abundant dopamine receptor in the brain. Intravenous therapeutic dopamine at low doses predominantly stimulates D_1 receptors, causing vasodilation. (However, high-dose therapeutic dopamine sufficiently occupies α and β receptors to cause vasoconstriction and increase blood pressure.)

D_2-like family of receptors (D_2, D_3, and D_4) couple to a different G protein, G_i that inhibits adenyl cyclase, thereby reducing intracellular cAMP, opening potassium channels, and decreasing the influx of calcium. D_2 receptors are predominately presynaptic receptors that are located on sympathetic nerves. Activation of D_2 receptors inhibits the synaptic release of norepinephrine and also inhibits the transmission of nerve impulses at sympathetic ganglia. Pituitary lactotroph cells also express D_2 receptors, whose activation inhibits the secretion of prolactin.

Regulation of Sympathoadrenal Activity

The rate of catecholamine secretion largely determines sympathoadrenal activity. However, adrenergic receptors and postreceptor events are sites of fine regulation.

As noted earlier, norepinephrine and epinephrine released during nerve stimulation bind to presynaptic alpha$_2$ receptors and
FIGURE 11–7   Activation of β- and α_2-adrenergic responses: activation vs inhibition of adenyl cyclase. Beta receptor ligands activate the stimulatory G protein, G_s, which leads to the dissociation of its $G\alpha_s$ subunit, charged with GTP. The activated $G\alpha_s$ subunit directly activates adenyl cyclase, resulting in increased cAMP that binds to the regulatory subunit (R) of the cAMP-dependent protein kinase, leading to the liberation of active catalytic subunits (C) that phosphorylate specific enzyme substrates and modify their activity. These catalytic units also phosphorylate the cAMP response element–binding protein (CREB), which modifies gene expression. Alpha$_2$ adrenoreceptor ligands inhibit adenyl cyclase by causing dissociation of the inhibitory G protein (G_i) into its subunits; that is, the α_i subunit charged with GTP and a βγ unit. The mechanism by which these subunits inhibit adenyl cyclase is uncertain. See Table 11–3 and text for physiologic effects of β and α_2 receptor activation. (Reproduced with permission from Katzung BJ. *Basic & Clinical Pharmacology*. 12th ed. New York: McGraw-Hill Education; 2012.)

reduce the amount of norepinephrine released. CgA is secreted from neurosecretory vesicles, along with catecholamines. Catestatin, a fragment of CgA, blocks postreceptor cells' cholinergic receptors, thereby inhibiting sympathoadrenal activity.

The binding of a catecholamine agonist to its receptor reduces the number of receptors on the effector cell surface by a process called down regulation. Catecholamine receptor antagonists do not cause down regulation of receptor expression. The mechanisms involved in some of these changes are known. For example, phosphorylation of the β-adrenergic receptor by β-adrenergic receptor kinase results in sequestration of the receptors into membrane vesicles, where they are internalized and degraded. The phosphorylated receptor also has a greater affinity for β-arrestin, another regulatory protein, which prevents its interaction with $G_s\alpha$.

Thyroid hormone increases the number of β receptors in the myocardium. Estrogen increases the number of α-adrenergic receptors in the myometrium and increases the affinity of some vascular α-receptors for norepinephrine.

Actions of Circulating Catecholamines (Tables 11–3 and 11–4)

Norepinephrine activates α_1-adrenergic receptors, increasing the influx of calcium into the target cell. Vascular α_1-adrenergic receptors are found in the heart, papillary dilator muscles, and smooth muscle. Activation of α_1-adrenergic receptors causes hypertension, increased cardiac contraction, relaxation of smooth muscle, and dilation of the pupils. Alpha$_1$-adrenergic activation stimulates sweating from non-thermoregulatory apocrine stress sweat glands, which are located on the palms, axillae, and forehead. Norepinephrine also activates β_1-adrenergic receptors that increase cardiac contraction and rate; stimulation of the heart rate is opposed by simultaneous vagal stimulation. Norepinephrine has less affinity for β_2-adrenergic receptors. However, with higher circulating norepinephrine levels, hypermetabolism and hyperglycemia are noted. Norepinephrine also activates β_3-adrenergic receptors on fat cells, causing lipolysis and an increase in serum levels of free fatty acids.

TABLE 11–4 Plasma levels of catecholamines required to produce hemodynamic and glucose effects.

	Norepinephrine	Epinephrine
Systolic blood pressure	↑ at 2500 pg/mL (15 nmol/L)	↑ at 500 pg/mL (3 nmol/L)
Diastolic blood pressure	↑ at 2500 pg/mL (15 nmol/L)	↓ at 500 pg/mL (3 nmol/L)
Pulse	↓ at 2500 pg/mL (15 nmol/dL)	↑ at 250 pg/mL (1.5 nmol/L)
Plasma glucose	↑ at 2500 pg/mL (15 nmol/L)	↑ at 250-500 pg/mL (1.5-3 nmol/L)

Data from Silverberg AB, et al, *Am J Physiol*. 1978;234:E252; and from Clutter WE, et al, *J Clin Invest*. 1980;66:94.

Epinephrine also stimulates α_1- and β_1-adrenergic receptors, with the same effects noted earlier for norepinephrine. However, epinephrine also activates β_2 receptors, causing vasodilation in skeletal muscles. Epinephrine thus has a variable effect on blood pressure ranging from hypertension to hypotension (rare). Hypoglycemia is a strong stimulus for the adrenal medulla to secrete epinephrine, which increases hepatic glycogenolysis. Epinephrine stimulates lipolysis, resulting in increased serum levels of free fatty acids. Epinephrine also increases the basal metabolic rate. Epinephrine does not cross the blood–brain barrier well. However, high serum levels of epinephrine do stimulate the hypothalamus, resulting in unpleasant sensations ranging from nervousness to an overwhelming sense of impending doom.

Dopamine is an important central neurotransmitter and a precursor to norepinephrine and epinephrine. However, most circulating dopamine is actually derived from the gastrointestinal tract from local synthesis and dietary sources. Dopamine synthesized by the intestines does not function as a neurotransmitter but rather as a paracrine hormone, affecting intestinal motility, blood flow, and sodium transport. Dopamine is also synthesized in the proximal renal tubule where it is a natriuretic hormone. Dopamine synthesis is increased by a high-salt diet. The renal dopamine-paracrine system accounts for the relatively large amounts of dopamine that are normally found in the urine. Circulating dopamine is not normally a significant catecholamine. High serum concentrations of dopamine stimulate vascular D_1 receptors, causing vasodilation and increased renal blood flow. Extremely high serum levels of dopamine are required to sufficiently activate vascular α_1 receptors to cause vasoconstriction.

Physiologic Effects of Catecholamines

A. Cardiovascular effects The release or injection of catecholamines generally increases heart rate and cardiac output and causes peripheral vasoconstriction, leading to an increase in blood pressure. The infusion of catecholamines also leads to a rapid reduction in plasma volume. These events are modulated by reflex mechanisms, so that, as the blood pressure increases, reflex vagal parasympathetic stimulation may slow the heart rate and tend to reduce cardiac output. Although norepinephrine usually has these effects, the effect of epinephrine may vary depending on the smooth muscle tone of the vascular system at the time. For example, in an individual with increased vascular tone, the net effect of small amounts of epinephrine may be to reduce the mean blood pressure through vasodilation, despite an increase in heart rate and cardiac output. In an individual with a reduction in vascular tone, epinephrine increases blood pressure. In addition cardiovascular function is integrated by the central nervous system, so that, under appropriate circumstances, one vascular bed may be dilated while others remain unchanged. The central organization of the sympathetic nervous system is such that its basal regulatory effects are quite discrete—in contrast to periods of stress, when stimulation may be rather generalized and accompanied by release of catecholamines into the circulation.

B. Effects on extravascular smooth muscle Catecholamines have effects on smooth muscle in tissues other than blood vessels. These effects include contraction (α_1) and relaxation (β_2) of uterine myometrium, relaxation of intestinal and bladder smooth muscle (β_2), contraction of the smooth muscle in the bladder (α_1) and intestinal sphincters, relaxation of tracheal smooth muscle (β_2), and pupillary dilation (α_1).

C. Metabolic effects Catecholamines increase oxygen consumption and heat production. This effect is mediated by β_1 receptors. Catecholamines also regulate glucose and fat mobilization from storage depots. Glycogenolysis in heart muscle and liver leads to an increase in available carbohydrate for utilization. Stimulation of adipose tissue leads to lipolysis and the release of free fatty acids and glycerol into the circulation. In humans, these effects are mediated by the β receptor. Both α_1 and β_2 receptors stimulate hepatic glycogenolysis and gluconeogenesis, which causes the release of glucose into the circulation. Both receptors are activated by epinephrine, which is particularly effective in raising hepatic glucose production. Plasma levels of catecholamines required to produce some cardiovascular and metabolic effects in humans are shown in Table 11–4.

Catecholamines have effects on water, sodium, potassium, calcium, and phosphate excretion in the kidney. Stimulation of the β_1 receptor increases the secretion of renin from the renal juxtaglomerular apparatus, thereby activating the renin-angiotensin system. This leads to stimulation of aldosterone secretion.

DISORDERS OF THE ADRENAL MEDULLA AND PARAGANGLIA

EPINEPHRINE AND NOREPINEPHRINE DEFICIENCY

Epinephrine is the major catecholamine secreted by the normal adrenal medulla, and its secretion is unique to the adrenal medulla. Epinephrine is usually deficient in cortisol deficiency of any cause, because high local concentrations of cortisol in the

adrenal medulla are necessary for transcription of the enzyme PNMT, which catalyzes the conversion of norepinephrine to epinephrine in the catecholamine biosynthetic pathway. Primary autoimmune adrenal cortical insufficiency produces epinephrine deficiency. Hypothalamic/pituitary ACTH deficiency also causes cortisol deficiency and consequently epinephrine deficiency.

Autonomic Insufficiency (Table 11–5 and Figure 11–8)

Autonomic insufficiency is also known as dysautonomia. It refers to a general reduction in autonomic activity. Since the adrenal medulla is part of the autonomic nervous system, there is usually an associated deficiency in circulating epinephrine. Autonomic insufficiency most commonly occurs in patients with longstanding type 1 diabetes mellitus. Diabetic autonomic neuropathy may be due to glucose neurotoxicity, but may also be due to autoimmunity. In one study of middle-aged patients with type 1 diabetes mellitus, 52% had complement-fixing antibodies against the sympathetic ganglia and 35% had antibodies against the adrenal medulla. They have minor defects in recovery from insulin-induced hypoglycemia (Figure 11–8), but in patients with diabetes mellitus in whom the glucagon response is also deficient, the additional loss of adrenal medullary response leaves them more susceptible to bouts of severe hypoglycemia. This is the result of a decrease in the warning symptoms as well as an impaired response to the hypoglycemia (see Chapters 17 and 18). Patients with generalized autonomic insufficiency usually have orthostatic hypotension. Familial dysautonomia can manifest as orthostatic tachycardia; norepinephrine transporter deficiency has been determined to be one cause of this condition. The causes of disorders associated with autonomic insufficiency are listed in Table 11–5.

When a normal individual stands, a series of physiologic adjustments occur that maintain blood pressure and ensure adequate circulation to the brain. The initial lowering of the blood pressure stimulates the baroreceptors, which then activate central reflex mechanisms that cause arterial and venous constriction, increase cardiac output, and activate the release of renin and vasopressin. Interruption of afferent, central, or efferent components of this autonomic reflex results in autonomic insufficiency.

Patients with generalized autonomic insufficiency usually have orthostatic hypotension; the reduction in blood pressure on
FIGURE 11–8 Plasma glucose, epinephrine, and norepinephrine levels after insulin administration in 14 normal subjects (━●━) and 7 patients with idiopathic orthostatic hypotension (━●━) with low or absent epinephrine responses. Results are expressed as mean ± SEM. (Reproduced with permission from Polinsky RJ et al. The adrenal medullary response to hypoglycemia in patients with orthostatic hypotension. *J Clin Endocrinol Metab*. 1980 Dec;51(6):1401-1406.)

TABLE 11–5 Disorders causing epinephrine or norepinephrine deficiency.

Diabetes mellitus autonomic neuropathy (glucose toxicity or autoimmunity): serum norepinephrine low

Wolfram syndrome: diabetes insipidus, diabetes mellitus, optic atrophy, deafness (DIDMOAD): serum norepinephrine low

Neurological diseases associated with autonomic neuropathy: serum norepinephrine low

Pure autonomic failure: serum norepinephrine and epinephrine low

Primary adrenocortical insufficiency: serum epinephrine low

Congenital adrenal hyperplasia: serum epinephrine low

Allgrove syndrome: achalasia, ACTH resistance, alacrima (AAA syndrome): serum epinephrine low

standing that causes visual disturbances, lightheadedness, and even syncope. Symptoms tend to be worse upon awakening, after meals, in hot weather, and at high altitude. Many patients have supine hypertension, even when not taking hypertensive medication. Affected patients often have a fixed heart rate, sinus tachycardia, diminished sweating, reduced metabolic rate, heat intolerance, nocturia, and erectile dysfunction. Angina pectoris can sometimes occur in the absence of coronary atherosclerosis. Patients frequently have a neurogenic bladder with associated symptoms of frequency, nocturia, hesitancy, reduced urine stream, and recurrent urinary tract infections. Patients may also have gastroparesis and disordered gastrointestinal motility. Sleep apnea is common and death can occur during sleep from reduced respiratory drive.

The diagnosis of autonomic insufficiency can usually be made clinically in patients with typical symptoms and orthostatic blood pressure changes on examination. Additionally, plasma and urine norepinephrine levels are usually very low, sometimes only 10% of average normal in severely affected individuals. Plasma epinephrine levels are often low as well.

The treatment of symptomatic orthostatic hypotension is dependent on maintenance of an adequate blood volume. Physical measures should be employed, such as raising the foot of the bed at night, crossing the legs when sitting, and wearing full-leg fitted support stockings. Adequate hydration is important. **Fludrocortisone** is an effective drug treatment, causing volume expansion. However, fludrocortisone can cause hypokalemia, supine hypertension, and edema. **Midodrine** is an α_1-receptor agonist that must be administered every 8 hours, due to its short half-life of 3 to 4 hours. Midodrine's use is limited by common side effects that include severe supine hypertension, bradycardia, and erythema multiforme. Other adverse effects include pilomotor erection ("goose bumps"), pruritis, and urinary retention. Therefore, midodrine should only be used for patients with very symptomatic orthostatic hypotension who have failed other therapies. Octreotide has been used, either alone or in combination with midodrine, for patients with severe autonomic failure where other treatment measures have failed.

Droxidopa is a vasopressor drug that is converted to norepinephrine by dopa-decarboxylase in peripheral tissues. It is indicated for patients with neurogenic orthostatic hypotension due to autonomic nervous system disorders, including: Parkinson disease, multiple system atrophy, DBH deficiency, pure autonomic failure, and other autonomic neuropathies. Droxidopa induces peripheral arterial and venous vasoconstriction. It is administered orally, starting in doses of 100 mg three times daily and increasing every 1 to 2 days to a maximum of 600 mg three times daily. Droxidopa can cause headache, dizziness, nausea; it also cause supine hypertension that responds to elevating the head and torso during sleep.

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Both PHEO and non–head-neck paraganglioma (PGL) are tumors of the sympathetic nervous system. Although they are similar tumors, they warrant distinction from each other to emphasize their differences in the following: (1) locations, (2) manifestations, (3) secretion profiles, (4) genetic syndromes, (5) difficulty of surgical resection, and (6) propensity to metastasize.

PHEOs are tumors that arise from the adrenal medulla, whereas non–head-neck PGLs arise from the ganglia of the sympathetic nervous system. PHEOs are more common (85%), and may be bilateral (17%). Patients with adrenal PHEOs are less likely to develop detectable metastases (11%) compared to PGLs (30%).

Prevalence

Among adult patients with hypertension, the prevalence of PHEO/PGL is between 0.2% and 0.6%. In children with hypertension, the prevalence of PHEO/PGL is about 1.7%. Nearly 5% of incidentally discovered adrenal masses are found to be PHEOs; about 9% of patients with such PHEOs are normotensive with normal tumor markers and atypical symptoms, particularly dizziness, or vertigo.

TABLE 11–6 Causes of death in patients with unsuspected pheochromocytomas.

Myocardial infarction
Cerebrovascular accident
Cardiac dysrhythmias
Irreversible shock
Renal failure
Dissecting aortic aneurysm
Acute respiratory distress syndrome

In the general population, PHEO and PGL tumors are diagnosed in about 2 to 8/million population yearly; nearly half of these present as an unexplained death. The National Cancer Registry in Sweden has reported that PHEOs/PGLs are discovered in about 2 patients/million people yearly. Autopsy series suggest a higher incidence, varying from about 250 cases/million to 1300 cases/million in a Mayo Clinic autopsy series. Retrospectively, 61% of PHEO/PGL tumors at autopsy occurred in patients who were known to have had hypertension; about 91% had the nonspecific symptoms associated with secretory PHEO/PGL tumors. In one autopsy study, a large number of patients with these tumors had nonclassic symptoms such as abdominal pain, vomiting, dyspnea, heart failure, hypotension, or sudden death (Table 11–6). Some patients have only intermittent hypertension or are not hypertensive at all, increasing the likelihood of missing the diagnosis. Considering these autopsy data, it is clear that the majority of PHEO/PGL tumors are not diagnosed during life. Tumors occur in both sexes and at any age. They are most commonly diagnosed in the fourth and fifth decades, but tend to present earlier in patients with germline mutations predisposing to PGL.

Pheochromocytomas are chromaffin tumors that arise from the adrenal medulla. They account for 90% of all PHEO/PGL tumors in adults and 70% in children. Adrenal PHEOs are usually unilateral (90%). Unilateral PHEOs occur more frequently in the right (65%) versus the left adrenal (35%). Right-sided PHEOs have been described as producing paroxysmal hypertension more often than sustained hypertension, whereas the opposite was true for tumors arising from the left adrenal. Adrenal PHEOs are bilateral in about 10% of adults and 35% of children. Bilateral PHEOs are particularly common (24% overall) in patients with familial pheochromocytoma syndromes caused by certain germline mutations (discussed later).

Basically, the adrenal medulla is a sympathetic ganglion whose neurons secrete neurotransmitters (epinephrine and norepinephrine) into capillaries instead of synapses. The adrenal medulla is surrounded by the adrenal cortex, with which it shares a portal system that bathes it in high concentrations of cortisol. Cortisol stimulates expression of the gene encoding PNMT, the enzyme that catalyzes the conversion of norepinephrine to epinephrine. Adrenal PHEOs nearly always secrete catecholamines with variable amounts of epinephrine as well as norepinephrine and their metanephrine metabolites. Metastases from adrenal PHEOs usually secrete only norepinephrine and its metabolite normetanephrine; they may rarely secrete epinephrine.

PHEOs are typically encapsulated by a true capsule or a pseudocapsule, the latter being the adrenal capsule. PHEOs are

firm in texture. Hemorrhages that occur within a PHEO can give the tumor a mottled or dark red appearance. A few *black* PHEOs have been described, with the dark pigmentation believed to be due to an accumulation of neuromelanin, a catecholamine metabolite. Larger tumors frequently contain large areas of hemorrhagic necrosis that have undergone cystic degeneration; viable tumor may be found in the cyst wall. Calcifications are often present. PHEOs can invade adjacent organs, and tumors may extend into the adrenal vein and the vena cava, resulting in pulmonary tumor emboli. PHEOs vary tremendously in size, ranging from microscopic to 3600 g. The average PHEO weighs about 100 g and is 4.5 cm in diameter.

Sympathetic PGLs (non head-neck) arise from sympathetic ganglia (Figure 11–9). They account for about 10% of all PHEO/PGL tumors in adults and about 30% in children. About 75% are intra-abdominal where they are often mistaken for adrenal PHEOs. PGLs are sometimes nonsecretory and may be confused with other neuroendocrine tumors. They arise most commonly in the perinephric, periaortic, and bladder regions but often found in the chest (25%), arising in the anterior or posterior mediastinum or the heart. Pelvic PGLs may involve the bladder wall, obstruct the ureters, and metastasize to regional lymph nodes. About 36% to 60% of paragangliomas are functional, secreting norepinephrine and normetanephrine. Functional status is not known to affect survival. Nonfunctional PGLs can often concentrate metaiodobenzylguanidine (MIBG) or secrete normetanephrine and CgA. PGLs of the bladder can cause symptoms associated with micturition; such symptoms occur particularly after voiding large amounts of urine, as upon arising in the morning. Large

perinephric tumors can cause renal artery stenosis and elevations in plasma renin activity. Vaginal tumors may cause dysfunctional vaginal bleeding. PGLs can rarely arise in central nervous system locations, including the sella turcica, petrous ridge, and pineal region. Cauda equina PGLs can cause increased intracranial pressure.

PGLs commonly metastasize (30%-50%) and present with pain or a mass. They tend to metastasize to the liver, lungs, lymph nodes, and bone. PGLs can be locally invasive and may destroy adjacent vertebrae and cause spinal cord and nerve root compression. PGL metastases usually secrete norepinephrine and normetanephrine. They do not secrete epinephrine and therefore do not typically cause significant weight loss, hyperglycemia, anxiety, or tremor.

Head-neck paragangliomas (HNPGL) are nonchromaffin tumors of parasympathetic ganglia. HN-PGLs occur with an incidence of 10 to 33 cases/million persons. Unlike chromaffin sympathetic paragangliomas, only about 5% of these tumors secrete catecholamines. However, about 23% secrete dopamine, and serum dopamine levels can be a useful tumor marker for patients whose dopamine levels are elevated prior to surgical resection. **Carotid body tumors (chemodectomas)** are PGLs that arise near the carotid bifurcation. They usually present as a painless neck mass near the carotid that sometimes has a bruit. Carotid body tumors can injure the vagus or hypoglossal nerves and can metastasize. **Jugulotympanic PGLs** arise in the middle ear and cause tinnitus, hearing loss, and dizziness. The tumor may be seen as a reddish-blue colored pulsating mass behind an intact tympanic membrane (*red drum*) that blanches when pressure is applied with a pneumatic ear speculum (Brown sign). **Glomus jugulare PGLs** arise in the jugular foramen. They often cause tinnitus and hearing loss as well as compression of cranial nerves, resulting in dysphagia. Vagal PGLs are rare, usually presenting as a painless neck mass often associated with hoarseness or dysphagia. Head-neck PGLs can also arise in the larynx, nasal cavity, nasal sinuses, and thyroid gland. Head-neck PGLs themselves are of more interest to otolaryngologists than endocrinologists. But they may be seen along with sympathetic PHEO/PGL in familial PGL syndromes, particularly those with germline SDHD and SDHC mutations (discussed later).

Nonchromaffin HN-PGLs behave differently from sympathetic PHEO/PGLs, although they are embryologically related to chromaffin sympathetic PGLs and may arise concurrently with sympathetic PGLs in familial PGL syndromes. These tumors are less likely to be malignant, although their indolence can be deceiving; recurrence and metastases may not appear for many years. Metastases to local nodes, lungs, and bone can occur. Long-term surveillance for recurrence or metastases is recommended for all patients. These tumors can produce CgA, and preoperative determination of CgA is recommended to determine if it will be a good serum marker for tumor recurrence. About 45% of patients with HN-PGLs carry *SDHx* germline mutations. About 33% harbor SDHD mutations; about 9% have SDHB mutations; about 4% have SDHC mutations. Therefore, gene sequencing is strongly recommended for all patients with HN-PGLs. Individuals harboring such germline mutations are prone to multiple and bilateral
FIGURE 11–9 Left: Anatomic distribution of extra-adrenal chromaffin tissue in the newborn. **Right:** Locations of extra-adrenal PHEOs reported before 1965. (Reproduced with permission from Coupland R. The Natural History of the Chromaffin Cell. *Longmans Green*; 1965.)

HN-PGLs and must also be screened for PGL/PHEO tumors outside the neck (see Genetic Conditions Associated with Pheochromocytomas and Paragangliomas, discussed later).

Neuroblastomas, ganglioneuroblastomas, and ganglioneuromas are sympathetic nervous system tumors that are related to PHEOs and likewise arise from embryonal sympathogonia (see Figure 11–1). Neuroblastoma is the most common malignant disease of infancy and the third most common pediatric cancer, accounting for 15% of childhood cancer deaths.

Ganglioneuroblastomas are composed of a mixture of neuroblasts and more mature gangliocytes; these develop in older children and tend to run a more benign course. Ganglioneuromas are the most benign of these tumors and are composed of gangliocytes and mature stromal cells.

Despite catecholamine secretion, children with neuroblastomas tend to be more symptomatic from their primary tumor or metastases than from catecholamine secretion. Tumors tend to concentrate radiolabeled MIBG, making it a useful imaging and therapeutic agent. Treatment of malignant tumors consists of surgery, chemotherapy, external beam radiation to skeletal metastases, and high-dose ^{131}I-MIBG therapy for patients with MIBG-avid tumors.

Screening for Pheochromocytomas and Paragangliomas

Hypertension is defined in adults as either a systolic blood pressure over 140 mm Hg or a diastolic blood pressure over 90 mm Hg. Hypertension is an extremely common condition, affecting about 20% of all American adults and over 50% of adults over 60 years of age. The incidence of PHEO/PGL is estimated to be less than 0.1% of the entire hypertensive population, but it is higher in certain subgroups whose hypertension is labile or severe. The risk for PHEO/PGL also appears to be higher in patients who have had cyanotic congenital heart disease, possibly due to stimulation of hypoxia-sensitive pathways in the adrenal medulla and paraganglia. Screening for PHEOs should be considered for such patients with severe hypertension and also for hypertensive patients with suspicious symptoms (eg, headaches, palpitations, sweating episodes, or unexplained bouts of abdominal or chest pains; Table 11–7).

Genetic Conditions Associated with Pheochromocytomas and Paragangliomas (Tables 11–8 through 11–12)

PHEOs and **PGLs** usually appear to occur sporadically, with only about 10% to 15% of affected patients readily giving a family history compatible with a familial germline mutation. However, 30% to 40% of patients with PHEO/PGL harbor a germline mutation predisposing to the tumor. This disparity is due to variable penetrance for PHEO/PGL, undiagnosed PHEO/PGL among family members with hypertension and sudden death, and patients' incomplete knowledge of their family's medical history. Mutations in multiple different genes have been demonstrated to predispose to familial PHEO/PGL (Table 11–8). Somatic mutations are

Gene Mutation
Cluster 1A:
VHL2: von Hippel Lindau Type 2
      VHL Type 2A
      VHL Type 2B
      VHL Type 2C
EGLN2: Prolyl Hydroxylase Domain 1 (PHD1)
EGLN1: Prolyl Hydroxylase Domain 2 (PHD2)
EPAS1-HIF2A: Hypoxia-Inducible Factor-2α (HIF-2α)

Cluster 1B:
SDHA: Succinate Dehydrogenase complex subunit A: PGL5[**]
SDHB: Succinate Dehydrogenase complex subunit B: PGL4[**]
SDHC: Succinate Dehydrogenase complex subunit C: PGL3[**]
SDHD: Succinate Dehydrogenase complex subunit D: PGL1[**]
SDAF2: Succinate Dehydrogenase Assembly Factor 2: PGL2[**]
MDH2: Malate Dehydrogenase 2
FH: Fumarate Hydratase

Cluster 2:
RET: Multiple Endocrine Neoplasia Type 2 (MEN 2)
      MEN 2A
      MEN 2B
NF-1: von Recklinghausen Neurofibromatosis 1
KIF1β: Kinesin Family member 1β
MAX: Myc-Associated factor X
TMEM127: Transmembrane protein 127

[**]Familial Paraganglioma/Pheochromocytoma (PGL/PHEO) syndrome.

TABLE 11–9 Suggested lifetime surveillance protocol for individuals with a *VHL2* germline mutation.

Patient self-monitors blood pressure regularly and reports hypertension or suspicious symptoms.
Age 10-15 years: Yearly retinal examination and blood pressure measurement; plasma free normetanephrine levels.
Age >15 years: Twice yearly physical examinations with blood pressure measurement; plasma free normetanephrine.
For suspicious symptoms and before major surgical procedures and pregnancy: biochemical screening for pheochromocytoma with plasma free normetanephrine.
Every 2 years: MRI scanning (with intravenous contrast) of the entire brain and spinal cord (VHL types 2A and 2B VHL); MRI scanning of the abdomen.
For abnormal biochemical screening: MRI or CT scan of the abdomen (nonionic contrast) with thin-section adrenal cuts; ^{123}I-MIBG SPECT or ^{18}F-FDA PET scan to confirm the identity of small masses.

TABLE 11–11 Suggested lifetime surveillance protocol for individuals carrying a *RET* proto-oncogene germline mutation.

Patient self-monitors blood pressure regularly and reports hypertension or suspicious symptoms.
Twice yearly: physical examination with blood pressure and neck examination; plasma free metanephrine; serum calcium and albumin (serum PTH if *RET* codon 634 mutation); serum calcitonin (patients with intact thyroid or with medullary thyroid carcinoma).
Prophylactic thyroidectomy: by age 5 years for MEN 2A and by 6 months for codon 918 mutations (MEN 2B).
Yearly thyroid ultrasound for patients with an intact thyroid.
For rising or elevated serum calcitonin levels after thyroidectomy: close surveillance for medullary thyroid carcinoma is required. [18]FDG-PET-CT fusion scans are particularly helpful.
For suspicious symptoms and before major surgical procedures and pregnancy: biochemical screening for pheochromocytoma with plasma free metanephrine.
For abnormal biochemical screening for pheochromocytoma: MRI or CT scan of the abdomen (nonionic contrast) with thin-section adrenal cuts; ^{123}I-MIBG SPECT or ^{18}F-FDA PET scan to confirm the identity of small masses.

common in sporadic PHEO/PGL. An underlying somatic mutation can be detected in 65% to 80% of all cases of PHEO/PGL.

About 20% of patients with an apparently sporadic single PHEO/PGL and no known family history of PHEO/PGL can be shown to harbor a germline mutation, if extensive genetic testing is performed. Such unsuspected germline mutations are more prevalent in PGLs than in PHEOs. For example, about 9% of patients with apparently sporadic, unilateral PHEOs have been found to have von Hippel-Lindau (VHL) mutations. Genetic testing is advisable for all patients with a PHEO/PGL. Genetic testing is strongly recommended for patients with extra-adrenal paragangliomas or multifocal tumors, onset of symptoms before age 45 years, prior history of head-neck PGL, family history of PHEO/PGL or other tumors associated with MEN 2 or VHL. Genetic screening

is also performed for patients with other manifestations of genetic syndromes noted later. Commercial genetic screening is available. Ambry Genetics offers a panel (PGLNext) that screens 12 genes for germline mutations and deletions that predispose to PHEO/PGL: *FH, MAX, MEN 1, NF-1, RET, SDHA, SDHAF2, SDHB, SDHC, SDHD, TMEM127, and VHL. Neurofibromatosis* is usually diagnosed clinically without genetic testing, since the clinical manifestations of NF-1 are usually unmistakable and the *NF-1* gene is very large and costly to sequence.

Known germline mutations that predispose to PHEO/PGL have been categorized into two clusters, according to their reputed common underlying mechanisms of tumorigenesis. Patients who harbor such germline mutations require close surveillance. Suggested lifetime surveillance protocols for patients with the most frequent germline mutations are presented in Tables 11–9 to 11–12.

Cluster 1 germline or somatic mutations involve genes that cause a pseudohypoxia signature that triggers an overabundance of hypoxia inducible factor (HIF), which promotes angiogenesis and cell division. Patients harboring mutations in this cluster might be sensitive to hypoxia. Individuals harboring SDHD germline mutations who live at high altitude have been shown to develop

TABLE 11–10 Suggested lifetime surveillance protocol for individuals with a germline *SDHB, SDHC*, or paternally-inherited *SDHD* mutation.

Patient self-monitors blood pressure regularly and reports hypertension or suspicious symptoms.
Twice yearly: physical examination and blood pressure; plasma-fractionated free metanephrines and serum CgA.
Yearly: scanning with ultrasound of the neck, abdomen, and pelvis.
Every 3 years: MRI of the chest, abdomen, and pelvis to detect early PHEO/PGL and renal cell carcinoma (RCC).
MRI of the head and neck (SDHC, paternal SDHD mutations) to detect head-neck PGL and jugular tympanicum PGL.
For suspicious symptoms and before endoscopies, major surgical procedures, and pregnancy: complete biochemical screening for pheochromocytoma with fractionated plasma metanephrines and serum chromogranin A.
For patients with epigastric discomfort: upper endoscopy, due to incidence of gastrointestinal stromal tumors (GIST).
For patients with headache, amenorrhea, hypogonadism, or clinical suspicion for a pituitary adenoma: biochemical evaluation and MRI for pituitary adenoma.
For abnormal biochemical screening: MRI or CT scan (nonionic contrast) of the chest, abdomen, and pelvis or ^{18}F-FDG-PET with CT fusion scan; to confirm ambiguous results: ^{123}I-MIBG SPECT or ^{18}F-FDA PET scan.

TABLE 11–12 Suggested lifetime surveillance protocol for individuals carrying a *NF-1* gene mutation.

Patient self-monitors blood pressure regularly and reports hypertension or suspicious symptoms.
Twice yearly: physical and neurologic examination and blood pressure, and a careful examination of the skin for development or growth of neurofibromas.
Yearly: CBC with WBC differential; plasma-fractionated free metanephrines; complete eye examination with visual fields.
Before major surgical procedures and pregnancy: plasma-fractionated free metanephrines to screen for pheochromocytoma.
For abnormal biochemical screening: MRI or CT scan of the abdomen (nonionic contrast); ^{123}I-MIBG SPECT or ^{18}F-FDA PET scan.

more PGLs that present earlier in life, compared to other affected members of their kindred living at sea level. However, it is not known whether altitude affects tumorigenesis in kindreds with other germline mutations. Whether other causes of chronic hypoxia (eg, sleep apnea, chronic obstructive pulmonary disease) might have a tumor-promoting effect upon these patients is also unknown. VHL disease is the most common condition associated with Cluster 1A mutations. Mutations in *PHD1, PHD2, and HIF2A* can also predispose to PHEO/PGL. Germline mutations in the gene Cluster 1B mutations encode proteins that are critical for oxidative metabolism in the tricarboxylic acid (TCA) cycle, also known as the citric acid cycle or Krebs cycle. These include mutations in the following: *SDHA, SDHB, SDHC, SDHD, SHAF2, MDH2,* and *FH.*

A. Cluster 1A Mutations

1. **von Hippel-Lindau (*VHL*) 3p25.3** The *VHL* gene is a tumor suppressor gene that encodes two different proteins (pVHL) of 213 and 160 amino acids. Both gene products have a role in the degradation of the hypoxia-inducible factors (HIF-1α and HIF-2α) as follows: the pVHL proteins have an α domain that binds with the protein elongin. The β domain of pVHL is open to bind HIF that has been hydroxylated, a reaction that requires oxygen. This complex then binds ubiquitin that targets HIF for intracellular destruction by proteases. In this manner, well-oxygenated cells destroy HIF. Conversely, cells that are either oxygen-deprived or that lack functional pVHL cause an intracellular accumulation of HIF, a transcription factor that induces the production of vascular endothelial growth factor (VEGF), erythropoietin, erythropoietin receptor, glucose transporter-1, and platelet-derived growth factor-B; these proteins allow an adaptation to hypoxia, but, in excess, they are believed to enhance tumorigenesis.

A germline mutation in the *VHL* tumor suppressor gene has been identified in most families with VHL disease. About 60% of affected families have loss-of-function mutations (30% with truncated pVHL and 30% with large *VHL* gene deletions), resulting in type 1 VHL. About 40% have missense mutations, resulting in an amino acid substitution in pVHL, causing type 2 VHL (discussed later).

In patients with VHL disease, vascular tumors, particularly hemangioblastomas, renal cysts, and renal cell carcinomas, develop when there is a somatic second-hit on the wild-type allele in one cell; this can be caused by various spontaneous mutations (loss of heterozygosity) or promoter hypermethylation of the wild-type VHL allele. In these vascular tumors, a second-hit is usually necessary to cause sufficient accumulation of HIF to promote tumorigenesis. In contrast, PHEOs that develop in patients with type 2 VHL typically have a normal wild-type VHL allele. However, most VHL-associated PHEOs also demonstrate a somatic loss of chromosome 3 (94%) or chromosome 11 (86%).

Although certain VHL kindreds are predisposed to develop PHEOs, it is not the dominant tumor of this syndrome. PHEOs develop only in patients with type 2 VHL (discussed later), and these are different from sporadic PHEOs, in that they are less likely to be malignant, more likely to be bilateral, more likely to be asymptomatic, and and more likely to present at an earlier age. Adrenal medullary hyperplasia is not associated with PHEOs in VHL, in contrast to MEN 2. Although most VHL-associated PHEOs arise in the adrenal, extra-adrenal

sympathetic PGLs sometimes occur and head-neck parasympathetic PGLs have been described. The mean age of presentation for a PHEO/PGL in type 2 VHL is 28 years; the youngest reported patient was 5 years old. In VHL disease, most PHEO/PGLs are relatively small (average 3.6 cm) and are characterized by a thick vascular tumor capsule.

The different types and subtypes of VHL are as follows:

Type 1 VHL—Affected members of families with type 1 VHL do not develop PHEOs. They tend to have loss-of-function *VHL* gene mutations, particularly gene deletions, frameshifts, or truncations.

Type 2 VHL—Affected members of families with type 2 VHL mutations are prone to develop PHEOs. These patients carry VHL missense mutations. Type 2 VHL may be divided into subtypes as follows:
  a. **Type 2A VHL**—PHEOs, hemangioblastomas, *low* risk of renal cell carcinoma.
  b. **Type 2B VHL**—PHEOs, hemangioblastomas, *high* risk of renal cell carcinoma.
  c. **Type 2C VHL**—PHEOs, *no* hemangioblastomas, *no* renal cell carcinomas.

The prevalence of VHL is at least 1/36,000 persons. About 20% of cases are caused by de novo mutations and do not have a family history of VHL. VHL disease carriers are predisposed to multicentric hemangioblastomas in the retina (retinal angiomas), cerebellum, and spinal cord. Renal cysts and renal clear-cell carcinoma commonly develop.

Pancreatic lesions occur in about 70% of patients with VHL. Such lesions are usually discovered incidentally and are usually multiple cysts or cystadenomas. Although such lesions are usually benign, they can cause pancreatitis or jaundice by obstruction of the pancreatic duct or the bile duct, respectively. Pancreatic neuroendocrine tumors (pNETs) occur in up to 17% of cases and are usually multiple. NETs have also arisen outside the pancreas in the duodenum and gallbladder. In VHL disease, NETs tend to occur at a relatively early age of about 35 years. They are usually nonfunctioning. However, they may secrete CgA, which can be a useful tumor marker. Such NETs are usually indolent, particularly those with a diameter under 3 cm and a doubling-time of over 500 days; such NETs are often followed clinically with scanning every 2 years. However, larger and more aggressive NETs are more likely to be malignant and are usually resected. Only 60% are visible with somatostatin receptor scintigraphy.

Other endocrine abnormalities have been described in VHL disease, including hyperparathyroidism and an aggressive pituitary adenoma that secreted both prolactin and growth hormone.

Endolymphatic sac tumors may occur, resulting in hearing loss, vertigo, or ataxia. Adnexal cystadenomas of probable mesonephric origin (APMO) are found in many women with VHL. APMOs may develop in the ovary, broad ligament, vagina, uterine cervix, and vulva. Equivalent epididymal cystadenomas occur in men with VHL.

Genetic testing for VHL disease should be done in children born to a parent with known VHL disease. If VHL disease is suspected, but the family's VHL mutation is not known, the patient must be screened for point mutations by direct *VHL* gene sequencing of the entire coding region and splice junctions.

The clinical diagnosis of VHL disease is made when a patient with a known *VHL* gene mutation develops one tumor

typical of VHL. In patients without a known family history of VHL, a presumptive diagnosis of VHL is made when they develop two or more hemangioblastomas or a hemangioblastoma in association with a PHEO or clear-cell renal carcinoma. Similarly, VHL disease should be suspected in patients with multiple VHL-associated tumors or one VHL-associated tumor that presents at a young age (<50 years for PHEO or hemangioblastoma; <30 years for clear-cell renal carcinoma). Such patients should have *VHL* gene sequencing.

In a French series of 36 patients with PHEOs and VHL disease, PHEOs were the presenting tumor in 53%. PHEOs tended to develop at an early age and were bilateral in 42%; concurrent PGLs were present in 11%. Three of the 36 patients had a malignant PHEO. In 18% of these patients with VHL disease, PHEO was the only known manifestation. Approximately 9% of patients with apparently sporadic, unilateral PHEO have been found to harbor a germline VHL mutation. In certain regions of Europe, the percentage is up to 20%, due to a founder effect for the Tyr98His *black forest* mutation that is more common in kindreds with German ancestry.

PHEOs in VHL disease exclusively produce norepinephrine. Therefore, the metabolite of norepinephrine (normetanephrine) is also produced in these tumors. Plasma free normetanephrine levels are usually elevated when patients with VHL disease develop a PHEO. Therefore, plasma free normetanephrine is the best screening test for patients who harbor a type 2 *VHL* gene missense mutation.

In patients with VHL, a major risk to life is the development of a renal cell carcinoma. When an abdominal computed tomography (CT) scan detects a solid renal lesion, it must be removed. Even simple cystic renal lesions are considered premalignant, and their removal is advisable if renal function can be preserved. If renal cysts are observed, they must be followed every 6 months with dynamic thin-section CT scanning to search for characteristics of malignancy: growth, wall irregularity, or septation. Individuals carrying a *VHL* mutation must have close medical surveillance. A surveillance protocol is recommended in Table 11–9.

2. **Egg Laying Gene Nine (*EGLN*)** These genes encode hypoxia-inducible factor—prolyl hydroxylase (HIF-PH) proteins (ie, prolyl hydroxylase domain [PHD] proteins). PHD proteins are enzymes that hydroxylate hypoxia-inducible factor (HIF), marking it for degradation by the VHL ubiquitination complex. Malfunction of PHD proteins causes an increase in HIF, predisposing to congenital erythrocytosis and formation of PHEO/PGL tumors. PHD proteins exist as three isoforms: PHD1, PHD2, and PHD3, which are encoded by the *EGLN* homolog genes: *EGLN2, EGLN1,* and *EGLN3*, respectively. PHEO/PGL tumors have been described in patients with germline mutations in *EGLN2* and *EGLN1*. An additional mutation of the wild-type *EGLN* allele in an adrenal medulla or paraganglion is required to give rise to a sympathetic PHEO/PGL. In patients harboring *EGLN* germline mutations, available first-degree relatives have tested negative for the mutation, indicating that these may be early post-zygotic mutations. These gene mutations are different from *VHL* gene mutations, although both cause an increase in HIF, and provide an alternative mechanism for PHEO/PGL tumorigenesis.

EGLN2 **19q13.2**: This gene encodes the enzyme prolyl hydroxylase domain 1 (PHD1). Germline mutations in *EGLN2* are rare. The index case was a woman who presented at age 6 with erythrocytosis (borderline elevated serum erythropoietin levels) that required phlebotomies at age 10, hypertension and a PHEO at age 14 that was resected but recurred and metastasized to a thoracic periaortic lymph node. At age 48, she was found to have contralateral PHEOs, an aortocaval PGL, a pelvic PGL, and a bladder PGL.

EGLN1 **1q42.1**: This gene encodes the enzyme prolyl hydroxylase domain 2 (PHD2). Germline mutations in *EGLN1* are rare. The index case was a woman who presented at age 16 with erythrocytosis (borderline elevated serum erythropoietin levels) requiring phlebotomies. At age 39, she was found to have hypertension and a left PHEO and 2 PGLs in the left renal hilum. At age 60, a right PHEO and 3 periaortic PGLs were resected.

3. **Endothelial PAS1 (*EPAS1*) *aka* Hypoxia Inducible Factor 2A (*HIF2A*) 2p21-p16** The *EPAS1*-HIF2A gene encodes the protein eponymously known as endothelial PAS domain-containing 1 (EPAS1) protein or hypoxia inducible factor 2α (HIF-2α). Rare mutations in *EPAS1-HIF2A* cause a syndrome of early PHEO/PGL, somatostatinomas, and erythrocytosis. Mutations causing constitutive activation and prolonged half-life of HIF-2α are typically somatic mutations found in sporadic PHEO/PGL tumor tissue. However, patients with *EPAS1* constitutively activating germline mutations have been described. A familial PHEO/PGL syndrome has not been described with this gene. These appear to be post-zygotic germline mutations that affect only certain related tissues. The index case presented with erythrocytosis in early childhood and high serum erythropoietin levels. At age 35, he was found to have hypertension and a retroperitoneal PGL, followed by multiple additional PGLs with pulmonary and bone metastases. Other patients have been described with multiple PGLs being detected as early as age 14 years. Affected patients are also prone to develop duodenal or pancreatic somatostatinomas and retinal abnormalities with decreased visual acuity.

B. Cluster 1B Mutations: PHEO/PGL syndromes due to mutations involving the tricarboxylic acid cycle (TCA or Krebs cycle) Certain kindreds have a proclivity to develop multicentric head-neck PGLs, sympathetic PGLs, and adrenal PHEOs. They are now also known to be prone to develop renal cell carcinomas and pituitary adenomas. These autosomal dominant syndromes were originally called familial PGL syndromes, although some patients develop adrenal PHEOs. Four of the familial PGL syndromes are caused by mutations in three of the four genes encoding mitochondrial complex II or a gene encoding their assembly into succinate dehydrogenase, which catalyzes the conversion of succinate to fumarate in the mitochondrial Krebs cycle (citric acid cycle) ultimately leading to oxidative phosphorylation and ATP generation. The resultant accumulation of intracellular succinate prevents the degradation of HIF; high intracellular levels of HIF stimulate cell division and angiogenesis, thereby promoting tumorigenesis. The responsible mutations occur in the genes encoding the following: SDH subunit B (*SDHB, PGL 4*), SDH subunit C (*SDHC, PGL 3*), SDH subunit D (*SDHD, PGL 1*), and succinate dehydrogenase complex assembly factor 2 (*SDAF2,* PGL 2). SDHB encodes a catalytic subunit, while *SDHC* and *SDHD* encode membrane-anchoring subunits

involved in electron transport. *SDHC* and *SDHD* (paternal) have an autosomal dominant proclivity to develop PGLs; those with *SDHB* and *SDHD* mutations can also develop adrenal PHEOs. Overall, about 12% of patients with PGLs and PHEOs have been found to harbor one of these germline mutations.

These syndromes are caused by mutations in nuclear genes that encode 3 of the 4 subunits that comprise mitochondrial complex II (SDH) that oxidizes succinate to fumarate (Krebs cycle). The four subunits of the tetrameric SDH consist of a 70-kDa flavoprotein (SDHA), a 30-kDa iron-sulfur protein (SDHB), a 15-kDa subunit of cytochrome b (SDHC), and a 12-kDa subunit of cytochrome b (SDHD). SDHC and SDHD components of cytochrome b are integral mitochondrial membrane subunits anchoring the catalytic subunits SDHA and SDHB that are involved with the electron transport chain, transferring an electron to coenzyme Q (ubiquinone). SDH is essential for aerobic energy production and the TCA cycle. Genetic defects cause mitochondrial dysfunction making the cells functionally hypoxic. This leads to increased secretion of VEGF that is necessary for tumor growth. (*SDHA* germline mutations do not cause PGLs but rather cause Leigh syndrome, a fatal early-onset mitochondrial neurodegenerative disease.)

All patients with PGLs and PHEOs ideally should be tested for germline mutations in *SDH*; such testing is highly recommended for patients with neck PGLs (>15% have germline mutations), other PGLs (particularly multifocal PGLs or PHEOs), a family history of PGL or PHEO, and PGLs arising in patients with Dutch ancestry.

Carney-Stratakis syndrome: Some patients with loss-of-function mutations in *SDHB, SDHC,* or *SDHD* can develop the dyad of PGLs and gastric stromal sarcomas, which is known as **Carney-Stratakis syndrome**. Tumors present relatively early, with an average age of 24 years at diagnosis. Women and men are affected equally. The PGLs that develop in this syndrome are usually functional and develop in the abdomen, rather than head-neck region. In this syndrome, the condition is familial, and affected kindreds do not develop pulmonary chondromas, factors that distinguish it from Carney triad.

1. **Succinate Dehydrogenase complex subunit A (*SDHA*) 5p15**
   SDHA germline mutations are usually lethal. *SDHA* mutations are more typically somatic mutations that have been found in sporadic paragangliomas. This is also known as *PGL 5*.
2. **Succinate Dehydrogenase complex subunit B (*SDHB*) 1p36**
   SDHB germline mutations cause a familial PGL/PHEO syndrome known as *PGL 4*. Affected individuals are prone to develop PGLs all along the parasympathetic and sympathetic chains, from the neck to the pelvis, and can develop adrenal PHEOs as well; they are less prone to glomus tumors of the neck than individuals with *SDHD* mutations. Sympathetic PGLs that arise in patients with *SDHB* germline mutations are much more likely to be metastatic (35%) at the time of diagnosis than tumors seen in patients with *SDHD* germline mutations. In one kindred with a large *SDHB* exon 1 deletion, the phenotypic penetrance of PGL was 35% by age 40. There have been no clear genotype-phenotype correlations with different *SDHB* mutations. However, certain kindreds have a distinctly higher penetrance. Also, some point *SDHB* "mutations" may

be relatively benign genetic polymorphisms rather than pathological mutations. Due to the rarity of these tumors, the precise penetrance for each *SDHB* mutation has not been fully determined. Other malignancies may also be more common in patients with *SDHB* mutations. In one series of 53 patients, renal cell carcinoma was detected in two patients. Pediatric neuroblastoma has been described in a child with an *SDHB* exon deletion.

3. **Succinate Dehydrogenase complex subunit C (*SDHC*) 1q2**
   SDHC encodes a protein of the same name, also known as succinate dehydrogenase cytochrome b560 subunit, mitochondrial. The SDHC protein forms a transmembrane dimer with SDHD that anchors complex II (SDHB and SDHA) to the inner mitochondrial membrane. SDHB germline mutations cause a familial PGL/PHEO syndrome known as *PGL 3*. SDHC germline mutations predispose to parasympathetic HN-PGLs and sympathetic PGLs but not adrenal PHEOs. About 4% of patients with HN-PGLs harbor an *SDHC* germline mutation.
4. **Succinate Dehydrogenase complex subunit D (*SDHD*) 11q23** The resultant protein is also known as succinate dehydrogenase (ubiquinone) cytochrome b small subunit, mitochondrial (CybS). SDHD germline mutations cause a familial PGL/PHEO syndrome known as *PGL 1*. Only patients with paternally inherited *SDHD* gene mutations are predisposed to develop PGLs and PHEOs. Affected individuals are particularly prone to develop parasympathetic HN-PGLs that do not typically secrete catecholamines. About 15% of patients with HN-PGLs harbor this germline mutation. Patients with SDHD mutations are more prone to develop renal cell carcinoma and can also develop Carney-Stratakis syndrome: gastrointestinal stromal cell tumors (GIST); such tumors have an additional acquired somatic SDHD mutation in their normal wild-type gene.

In kindreds with *SDHD* gene mutations, only paternal transmission of the mutated gene causes the susceptibility to PGLs and PHEOs; this phenomenon is known as **maternal genomic imprinting**, meaning that the maternally inherited mutant gene does not cause the syndrome in the mother's offspring. A male who inherits an *SDHD* mutation from his mother does not express the phenotype (no PGLs) but can pass on the gene to his children, who can express the phenotype (PGL/PHEO). A female who inherits an *SDHD* mutation from her father develops PGL/PHEOs, but her children who inherit the *SDHD* mutation are not affected.

Individuals with *SDHD* germline mutations are particularly prone to develop HN-PGLs that arise from parasympathetic ganglia that are embryologically related to sympathetic paraganglia. These tumors do not usually secrete catecholamines and are known as **nonchromaffin** PGLs. Multicentric tumors have been reported in about 74% of PGL patients with *SDHD* mutations. About 50% of patients with seemingly isolated PHEOs and a germline *SDHD* mutation harbor a hidden PGL. Sympathetic PGLs and adrenal PHEOs (8%) also occur in affected individuals.

A founder *SDHD* mutation has been noted in families of Italian descent: *Q109X*. Three *SDHD* founder mutations have been discovered in families of Dutch ancestry: *Leu95Pro*, *Asp92Tyr,* and *Asp92Tyr*. An investigation of 243 family members with a paternally inherited *Asp92Tyr* mutation in SDHD reported the following. The risk of developing a PGL or PHEO was 54% by age 40 years, 68% by 60 years, and 87% by 70 years. Most patients had HN-PGLs, while some had

sympathetic PGLs and 8% had PHEOs. Multiple tumors were found in 65%.

Malignancy appears to be uncommon in patients with SDHD-associated PGLs. However, malignant neck PGLs can be indolent, and metastases to neck nodes, lungs, and bones may not be clinically evident for many years. Therefore, life-long surveillance is necessary (see Table 11–10).

5. **Succinate Dehydrogenase complex Assembly Factor 2 (*SDAF2*) 11q12.2** This gene is also known as *SDH5*. Germ-line mutations in *SDAF2* cause familial PGL syndrome type 2 (PGL 2). The *SDAF2* gene is a member of a family of genes known as mitochondrial respiratory chain complex assembly factors. There appears to be maternal imprinting and only individuals with a paternally inherited mutated gene develop both PGLs and PHEOs. The most common mutation has been Gly78Arg.

6. **Malate Dehydrogenase 2 (*MDH2*) 7cen-q22** The *MDH2* gene encodes an enzyme of the TCA cycle. The index case for this germline mutation was a 55-year-old man who presented with multiple malignant PGLs.

7. **Fumarate Hydratase (*FH*) 1q42.1** The *FH* gene encodes another enzyme in the TCA cycle. Germline *FH* mutations predispose to familial leiomyomatosis and renal cell carcinoma (FLRCC). Affected individuals develop cutaneous and uterine leiomyomatosis type 2 papillary renal cell carcinoma, and PGLs. About 40% of PGLs have presented with metastatic disease.

Cluster 2 germline or somatic mutations cause an overexpression of RAS/MAPK and P13K-AKT-mTOR signaling pathways. Cluster 2 mutations include the following: (1) *RET* proto-oncogene activating mutations (Multiple Endocrine Neoplasia Type 2A, MEN 2A and MEN 2B); (2) von Recklinghausen Neurofibromatosis Type 1 (*NF-1*); (3) *KIF1β*; (4) *MAX*; and (5) *TMEM127*.

1. ***RET* proto-oncogene 10q11.2** *RET* is an abbreviation for the term "rearranged during transfection." Germline activating mutations in the *RET* proto-oncogene give rise to **multiple endocrine neoplasia type 2 (MEN 2A and MEN 2B)**.

The first description of PHEO was in a patient with MEN 2. In 1882, Felix Fränkel described PHEOs in an 18-year-old woman with bilateral adrenal tumors; genetic testing of four living relatives has revealed a germline mutation in the *RET* proto-oncogene.

The prevalence of MEN 2 has been estimated at 1 in 30,000. MEN 2 is an autosomal dominant disorder that causes a predisposition to medullary thyroid carcinoma, PHEO, duodenal or pancreatic somatostatinomas (rare), and other abnormalities described later. MEN 2 is caused by an activating mutation in the *RET* proto-oncogene on chromosome 10q11.2. *RET* consists of 21 exons that encode a transmembrane receptor tyrosine kinase that is expressed in neural crest tissues. The constitutive activation of *RET* causes hyperplasia in affected tissues, including the adrenal medulla. Additional mutation(s) are believed to be required for a PHEO to develop. The somatic loss of a tumor suppressor gene on chromosome 1p appears to be necessary for PHEO formation. Additionally, reduced expression of *NF-1* has been reported in a minority of PHEOs arising in patients with MEN 2 mutations.

MEN 2 kindreds can be grouped into two distinct subtypes: MEN 2A (90%) and MEN 2B (10%). Patients with MEN 2A have various single amino acid missense mutations affecting the extracellular *RET* domain that cause *RET* homodimerization and constitutive activation of its tyrosine kinase. Patients with MEN 2B have a particular missense mutation (codon 918, exon 16) affecting the intracellular domain at the *RET* tyrosine kinase's catalytic site, causing constitutive activation. In either subtype, PHEOs usually develop in the adrenals (96%); extra-adrenal paragangliomas are rare (4%). About 42% of patients with PHEO in MEN 2 have hypertension, usually paroxysmal. Overall, only about 53% exhibit symptoms of PHEO. Each specific type of mutation in the *RET* codon determines each kindred's idiosyncrasies, such as the age at onset and the aggressiveness of medullary thyroid carcinoma.

A limited number of *RET* gene exons have been found to harbor mutations that are capable of causing constitutive activation of the tyrosine kinase. *RET* exons 10, 11, 13, 14, 15, and 16 are usually involved. Therefore, routine genetic screening searches for mutations only in these exons. If no mutation is found in these exons, the remaining 15 exons can be sequenced in a research laboratory. When an affected kindred's *RET* mutation is already known, all first-degree relatives in the kindred should be screened for that specific mutation.

PHEOs arise in the adrenals, and extra-adrenal PGLs are uncommon in MEN 2. In patients with MEN 2, only about 4% of PHEOs are found to be metastatic, possibly because of earlier detection. When PHEOs develop in patients with MEN 2, they are bilateral in about two-thirds of cases; however, with close surveillance of affected kindreds, PHEOs are discovered earlier and are more likely to be unilateral. After a unilateral adrenalectomy for PHEO in a patient with MEN 2, a contralateral PHEO develops in about 50% of patients an average of 12 years after the first adrenalectomy. In patients with MEN 2, adrenal PHEOs produce norepinephrine and epinephrine (with its metabolite metanephrine). When screening for small PHEOs, plasma catecholamine concentrations may be normal, but plasma metanephrine concentrations are usually elevated, making plasma free metanephrines the screening test of choice for these patients. However, some PHEOs are detected only by a 24-hour urine determination for fractionated metanephrines, catecholamines, and creatinine.

MEN 2A (Sipple syndrome)—Patients with this genetic condition develop medullary thyroid carcinoma (95%-100%), hyperparathyroidism due to multiglandular hyperplasia (20%), and PHEO (50%; range 6%-100% depending on the kindred) or adrenal medullary hyperplasia. Patients with MEN 2A also have an increased incidence of cutaneous lichen amyloidosis and Hirschsprung disease.

Individuals belonging to an MEN 2A kindred should have genetic testing for *RET* proto-oncogene mutations by 5 years of age to determine if they carry the genetic mutation that will require prophylactic thyroidectomy and close surveillance for PHEO and hyperparathyroidism.

More than 85% of the mutations in MEN 2A families affect codon 634 in exon 11 of the *RET* proto-oncogene. PHEOs tend to present in middle age, often without hypertension. The exceptions are patients who harbor a *RET* C634R (arginine) germline mutation, in whom 59% develop bilateral PHEO by age 40 and who therefore require more intense surveillance for PHEO at an earlier age. Individuals with mutations in RET codon 630 also have a high incidence of PHEO. PHEOs also occur in most other kindreds with MEN 2A. Screening for PHEO should commence with the routine blood pressure measurements that are performed during examinations in childhood for medullary thyroid

carcinoma and follow-up of hypothyroidism following thyroidectomy. At about age 15 years, affected individuals should commence yearly screening for PHEO with plasma free metanephrine determinations.

Certain *RET* mutations (codons 609, 768, V804M, and 891) rarely produce PHEOs. Less intense screening for PHEOs is required in patients with these mutations.

MEN 2B—Over 90% of patients with MEN 2B have a single amino acid substitution of methionine to threonine on codon 918 in exon 16 that affects the intracellular domain of tyrosine kinase. About 50% of such mutations are familial while the rest arise de novo as post-zygotic mutations and are sporadic. Patients with this genetic condition are prone to develop mucosal neuromas, PHEO, adrenal medullary hyperplasia, and aggressive medullary thyroid carcinoma. About 50% of affected patients develop all three manifestations of the syndrome. Mucosal neuromas tend to develop first and occur in most patients. They appear as small bumps on the tongue, lips and buccal mucosa, eyelids, cornea, and conjunctivae. The lips and eyelids may become diffusely thickened. Intestinal ganglioneuromatosis occurs and alters intestinal motility, causing diarrhea or constipation and occasionally megacolon. Affected individuals have a marfanoid habitus with associated spinal scoliosis or kyphosis, pectus excavatum, a high-arched foot and talipes equinovarus (club foot) deformities. In patients with MEN 2B, medullary thyroid carcinoma tends to be aggressive and occurs at an earlier age than in patients with MEN 2A. Members of kindred with MEN 2B should immediately have genetic testing for their family's *RET* proto-oncogene mutation. If an individual is found to carry the family's *RET* mutation, early prophylactic thyroidectomy is advisable. In kindreds with MEN 2B, infants are screened for the mutation at birth. For affected infants, prophylactic thyroidectomy is performed by 6 months of age.

All individuals carrying a *RET* proto-oncogene mutation require close lifetime medical surveillance (see Table 11–11). See Chapter 22, Multiple Endocrine Neoplasia.

2. Neurofibromatosis Type 1 (*NF-1*) 17q11.2 PHEOs are ultimately diagnosed in 0.1% to 5.7% of patients with von Recklinghausen neurofibromatosis type 1 (NF-1). Most of these PHEOs are not diagnosed during life, since the autopsy incidence of PHEO in NF-1 patients is 3.3% to 13%. PHEOs that develop in patients with NF-1 are similar to sporadic PHEOs: 84% have solitary adrenal tumors, 10% have bilateral adrenal tumors, 6% have extra-adrenal PGLs, and 12% have metastases or local invasion.

PHEOs are present in 20% to 50% of NF-1 patients with hypertension, and all NF-1 patients with hypertension must be screened for PHEO. It is prudent to screen all patients with NF-1 for PHEO yearly, with interval testing if hypertension or symptoms develop that are suggestive of PHEO (headache, perspiration, palpitations). Similarly, all patients with NF-1 should be screened for PHEO before major surgical procedures and pregnancy.

In patients with NF-1, PHEOs can present anytime during life, from infancy to old age, with a mean age of 42 years at diagnosis. These PHEOs can grow to large size. Although patients with PHEOs may develop hypertension, many patients are surprisingly asymptomatic despite increased catecholamine secretion. Patients with NF-1 are prone to develop vascular anomalies such as coarctation of the aorta and renal artery dysplasia, which can produce hypertension and mimic a PHEO.

von Recklinghausen disease is caused by a mutation in the NF-1 tumor suppressor gene mapped to chromosome 17q11.2. The *NF-1* gene encodes a 2818 amino acid protein called neurofibromin, which inhibits *Ras* oncogene activity; loss of neurofibromin leads to *Ras* activation and tumor formation. It is a common autosomal dominant genetic disorder (although 50% of cases seem sporadic), with an approximate incidence of 300 to 400 cases per million population. Although genetic testing for NF-1 is available, the diagnosis is usually made clinically during childhood or adolescence.

Patients with *NF-1* mutations can present in childhood with optic gliomas that impair vision or in adolescence with plexiform neurofibromas. Patients develop visible subcutaneous neurofibromas and schwannomas of cranial and vertebral nerve roots. Skeletal abnormalities are common. Hypothalamic hamartomas may occur and cause precocious puberty. Iris hamartomas may occur and are known as Lisch nodules. NF-1 patients have an increased risk of developing other tumors, especially malignant peripheral nerve sheath tumors and leukemia (particularly juvenile chronic myelogenous leukemia). Affected patients can also develop pancreatic somatostatinomas. Patients may also have freckles in their axillae and skin folds. Multiple cutaneous pigmented café au lait spots develop and grow in size and number with age; most patients ultimately develop more than six spots (smooth bordered) measuring more than 1.5 cm in diameter.

Individuals carrying an *NF-1* mutation must have lifetime medical surveillance (see Table 11–12).

3. Kinesin Factor 1B (*KIF1B*) 1p36 *KIF1B* is a gene that is believed to synthesize a proapoptotic factor for sympathetic cell precursors. The gene is located on 1p36, where gene deletions have been noted in neural crest tumors. Rare mutations in *KIF1B* have been associated with PHEOs, PGLs, and neuroblastomas, as well as other tumors that are not of neural crest origin. These tumors are transcriptionally related to *NF-1* and *RET* tumors.

4. Myc-Associated factor X (*MAX*) 14q23 Germline mutations in the *MAX* gene predispose to PHEO/PGL. These rare mutations appear to arise from differential paternal transmission in this syndrome. About two-thirds of cases have been found to have multiple tumors or bilateral adrenal tumors that are synchronous or metachronous; such tumors display loss of heterozygosity in the wild-type *MAX* allele. About 10% to 37% of such tumors have metastasized by the time they are discovered.

5. Transmembrane protein 127 (*TMEM127*) 2q11.2 This gene encodes a tumor suppressor protein that controls a signaling pathway (mTORC1) that promotes cell proliferation and survival. Individuals with rare *TMEM127* germline mutations are prone to develop renal cell carcinomas and PHEOs/PGLs; such tumors have been found to have a second somatic mutation in *TMEM127*, resulting in loss of heterozygosity. Affected individuals usually present between ages 42-54 years, older than patients in some other familial PHEO/PGL syndromes. They usually develop adrenal PHEOs that are benign. About one-third of cases have bilateral adrenal PHEOs when discovered. However, secretory PGLs and HN-PGLs have been reported. Only about 25% of patients with *TMEM127* germline mutations give a family history of PHEO, so 75% appear to be "sporadic." *TMEM127* germline mutations are found in about 2% of all patients with PHEO/PGL. No other tumors have been definitely associated with germline *TMEM127* mutations.

Other genetic syndromes associated with PHEO or PGL:

1. **Carney-Stratakis syndrome** This familial syndrome is autosomal dominant and almost always associated with a detectable germline mutation in *SDHB*, *SDHC*, or *SDHD*. Both sexes are affected equally. Affected patients develop PHEO/PGL and gastrointestinal stromal cell tumors (GIST); such tumors have an additional acquired somatic SDHx mutation in their normal wild-type gene. The syndrome is also known as GIST-PGL dyad. This syndrome is *not* associated with pulmonary chondromas.

2. **Carney triad** Multicentric paragangliomas occur in patients with Carney triad. About 150 cases have been reported worldwide. About 10% of affected patients have been found to harbor germline mutations in *SDHA, SDHB,* or *SDHC* genes. However, for the remaining patients, the precise underlying genetic defect is unknown. This condition is not usually familial. Affected individuals are usually young women who develop malignant but indolent GISTs (leiomyosarcomas), pulmonary chondromas, and PHEO/PGLs. Only one-fifth of reported cases have had all three tumors, while most patients have had two of the three tumors, usually gastric sarcomas and pulmonary chondromas. Other tumors can develop in this syndrome, including ganglioneuromas, neuroblastomas, adrenocortical adenomas (12%), and esophageal leiomyomas. Women account for 86% of the cases. Tumors tend to develop early in life, with an average age of 21 years at diagnosis. This tumor syndrome is distinct from Carney-Stratakis syndrome (discussed earlier).

3. **Beckwith-Wiedemann syndrome** PHEOs have been reported in patients with Beckwith-Wiedemann syndrome and may be bilateral. Affected individuals also have other abnormalities, particularly neonatal hypoglycemia, omphalocele, umbilical hernia, macroglossia, and gigantism, and they are prone to develop malignancies.

Other genetic tumor syndromes that may possibly predispose to PHEO/PGL:

1. *ATM* **(Ataxia-Telangiectasia Mutated gene)** Homozygotes have ataxia-telangiectasia, immunodeficiency with respiratory infections, and an increased risk for breast cancer and lymphoid malignancies. At least one patient with an *ATM* germline mutation has developed a PHEO/PGL (author's experience).

2. *SETD2* **(Su[var], Enhancer of zeste, Trithorax-Domain containing 2)** Germline loss-of-function mutations in the *SETD2* gene predispose to renal cell carcinoma and childhood brain gliomas. At least one patient with an *SETD2* germline mutation has developed a PHEO/PGL (author's experience).

Somatic Mutations in PHEO and PGL

Somatic mutations have been found in nearly 50% of PHEO/PGLs. Somatic activating *HRAS* gene mutations have been found only in sporadic PHEO/PGL tumor tissue. The many different germline mutations that cause familial syndromes also occur as somatic mutations in sporadic PHEO/PGL tumors: (1) Activating somatic mutations in *RET and HIF2*; (2) Loss-of-function somatic mutations are predominantly seen for *NF-1*, and somatic mutations in *VHL, SDHB, SDHD,* and *MAX* are less common.

Somatic mutations have also been described for *EPAS1*. Somatic mutations in other genes have been reported in only a few PHEO/PGLs: *MEN 1, EGLN1, EGLN2, MDH2,* and *IDH1*. Other somatic mutations have been described in sporadic PHEO/PGL, but their role in tumorigenesis is uncertain: *TP53, ATRX,* and *BRAF*.

Physiology of PHEO and PGL

PHEOs are tumors that arise from the adrenal medulla, whereas non–head-neck PGLs arise from sympathetic nerve ganglia. Although some PHEOs/PGLs do not secrete catecholamines, most synthesize catecholamines at increased rates that may be up to 27 times the synthetic rate of the normal adrenal medulla (Figure 11–10). The persistent hypersecretion of catecholamines by most PHEOs/PGLs is probably due to lack of feedback inhibition at the level of tyrosine hydroxylase. Catecholamines are produced in quantities that greatly exceed the vesicular storage capacity and accumulate in the cytoplasm. Such catecholamines and their metabolites (metanephrine and normetanephrine) diffuse out of the PHEO/PGL tumor cells into the circulation.

In contrast to the normal adrenal medulla, most adrenal PHEOs produce more norepinephrine than epinephrine, while many produce both hormones. Some PHEOs produce epinephrine almost exclusively. Most PGLs produce mostly norepinephrine with some dopamine and no epinephrine. PGLs that produce large amounts of dopamine tend to be metastatic. Some PGLs secrete no catecholamines or metanephrines.

Serum levels of catecholamines correlate only modestly with tumor size. On average, large tumors secrete more catecholamines than smaller tumors. However, large tumors are much more variable in their secretion of tumor markers. This may be due to the fact that larger tumors tend to develop hemorrhagic necrosis and cysts that are not functional. Additionally, about 20% of large, malignant PGLs are less differentiated and are nonsecretory.

Severe hypertensive episodes occur in most patients with PHEOs and secretory PGLs. Exocytosis of catecholamines from the PHEO can play a role in such paroxysms, but most PHEOs have minor sympathetic innervation. Instead, hypertensive crises are often caused by spontaneous hemorrhages within the tumor or by pressure on the tumor causing the release of blood from venous sinusoids that are rich in catecholamines. Thus, catecholamines can be released by physical stimuli such as bending or twisting or by micturition in patients with bladder PGLs. Of course, surgical manipulation of such tumors releases catecholamines and can cause life-threatening hypertensive crises.

Chronically high circulating levels of catecholamines may cause normal sympathetic axons to become saturated with catecholamines due to active catecholamine neuronal uptake. This may account for the paroxysms of hypertension that are triggered by pain, emotional upset, intubation, anesthesia, or surgical skin incisions. Adrenergic catecholamine saturation may also explain the elevations in plasma and urine catecholamines that can occur for 10 days or longer after a successful surgical resection of a PHEO/PGL.

	pg/mL	
	Norepinephrine (nl <500 pg/mL)	**Epinephrine** (nl <250 pg/mL)
Superior vena cava	5500	100
Inferior vena cava	5700	530
Above right adrenal vein	6000	1200
Left adrenal vein	6400	47,000
Tumor		
Left renal vein	32,000	2300
Iliac vein	5000	150
FIGURE 11–10 Plasma norepinephrine and epinephrine levels in venous samples of blood from a patient with a secretory left perinephric PGL. Note that the level of epinephrine is very high in the left adrenal vein sample, distinguishing it from the drainage of the PGL that secretes norepinephrine into the left renal vein. Note the relatively normal peripheral levels of epinephrine (seen in the iliac vein or the superior vena cava). Such venous sampling is no longer required for diagnosis and localization of PHEO or PGL.

Secretion of Other Peptides by PHEOs and PGLs (Table 11–13)

Although PHEOs/PGLs secrete mainly catecholamines and their metabolites, they also secrete many other peptide hormones, many of which contribute to a patient's clinical symptoms. Secretion of parathyroid hormone–related peptide (PTHrP) can cause hypercalcemia. Ectopic ACTH production can cause Cushing syndrome. Erythropoietin secretion can cause erythrocytosis. Leukocytosis is frequently seen in patients with PHEO, probably caused by cytokine release from the tumor. Interleukin-6 secretion can cause fevers and acute respiratory distress syndrome (ARDS).

Chromogranin A: Chromogranins are acidic single-chain glycoproteins that are found in neurosecretory granules. They have been categorized into three classes: chromogranins A (CgA), CgB (secretogranin I), and CgC (secretogranin II). In humans, the gene for CgA is on chromosome 14 and encodes a molecule with 431 to 445 amino acids. CgA molecules aggregate with low pH or high calcium concentrations and promote the formation of secretory vesicles and the concentration of hormones within these vesicles.

CgA also acts as a prohormone. It is cleaved by endopeptidases into smaller peptides. CgA is the prohormone for the amino terminal fragments vasostatin I (CgA 1-76) and vasostatin II (CgA 1-115), which appear to inhibit vasoconstriction. CgA is also the prohormone for catestatin (CgA 352-372), which blocks acetylcholine receptors and thus inhibits adrenosympathetic activity.

Most PHEO/PGL tumors secrete CgA, and serum CgA levels may be assayed as a tumor marker for PHEO. However, CgA is

Tumor necrosis factor alpha (TNFα, cachexin)
Vasoactive intestinal polypeptide

[a]Pheochromocytomas and paragangliomas variably secrete different peptides. Not all peptides have been documented to produce clinical manifestations (see text).

not unique to the adrenal medulla. It is produced in neuroendocrine cells outside the adrenal medulla that secrete peptide hormones. CgA is found in the pituitary gland, parathyroid gland, central nervous system, and pancreatic islet cells.

Neuropeptide Y (NPY): Many PHEOs secrete significant amounts of NPY. The molecule is a 36 amino acid peptide (see primary sequence, discussed later) that is found in neurosecretory granules and is secreted along with catecholamines. It is a very potent nonadrenergic vasoconstrictor that contributes to hypertension in some patients with PHEO.

Tyr-Pro-Ser-Lys-Pro-Asp-Asn-Pro-Gly-Glu-Asp-AlaPro-Ala-Glu-Asp-Met-Ala-Arg-Tyr-Tyr-Ser-Ala-LeuArg-His-Tyr-Ile-Asn-Leu-Ile-Thr-Arg-Gln-Arg-Tyr-NH$_2$

NPY acts on G protein–coupled receptors, which belong to the pancreatic polypeptide family of cell-surface receptors called peptide YY (PYY). Six subtypes of these receptors have been identified (Y$_1$R-Y$_6$R). NPY has particular affinity for the Y$_1$-R, Y$_2$-R, Y$_3$-R, and Y$_5$-R receptors. Some PYY receptors are found in vascular smooth muscle and mediate NPY-induced vasoconstriction. Other PYY receptors are found on the pheochromocytes themselves and mediate NPY's autocrine effects: NPY appears to inhibit catecholamine synthesis via Y$_3$R, a receptor which blocks L-type Ca^{2+} channels. It inhibits catecholamine release via Y$_2$R, a receptor that blocks N-type Ca^{2+} channels.

NPY also has paracrine effects, stimulating endothelial cell proliferation and angiogenesis that may foster tumor growth. Patients with essential hypertension have normal levels of NPY. However, in a series of eight patients with PHEO, NPY levels were elevated 2- to 465-fold above the normal reference range. In another series, 59% of adrenal PHEOs were found to secrete NPY during surgical resection; high serum levels of NPY were observed to correlate with vascular resistance, independent of norepinephrine. NPY appears to contribute to hypertension and left ventricular hypertrophy in most patients with PHEO. In contrast, few PGLs secrete NPY.

Adrenomedullin (AM): It was originally isolated from a PHEO, thus its misleading name. Although AM is produced by the adrenal medulla, it is also produced in the adrenal cortex (zona glomerulosa). It is produced by so many other tissues that the adrenal gland is actually a minor source for circulating AM.

AM is a 52 amino acid peptide cleavage product of a prohormone, preproadrenomedullin, encoded on chromosome 11. AM has some homology with *calcitonin* gene–related peptide (CGRP), and exerts its effects as a ligand for CGRP1 receptors and specific AM receptors. Ligand binding to the G protein–coupled receptors causes adenylate cyclase activation and an elevation of cellular cAMP levels.

AM is a pluripotent hormone. In the adrenal, AM appears to suppress aldosterone secretion. It is also secreted by the heart, lung, kidney, and brain as well as vascular endothelium, where it causes vasodilation. AM is also a natriuretic peptide and is secreted by the heart in congestive heart failure. AM is expressed in PHEOs and a variety of other tumors, where it appears to stimulate tumor growth, reduce apoptosis, and suppress the immune response to the tumor.

Neuron-specific enolase (NSE): It is a neuroendocrine glycolytic enzyme. Serum levels of NSE have been reported to be normal in patients with benign PHEO but are elevated in about half of patients with malignant PHEOs. Therefore, an elevated serum level of NSE may increase the likelihood that a given PHEO is malignant.

Manifestations of PHEO and PGL (Table 11–14)

More than one-third of PHEOs and sympathetic PGLs cause death prior to diagnosis. Death usually results from a fatal cardiac dysrhythmia, myocardial infarction, stroke, cardiomyopathy, ARDS, or multisystem crisis. Adult patients with a secretory PHEO/PGL usually have paroxysmal symptoms, which may last minutes or hours; symptoms usually begin abruptly and subside slowly. The particular constellation of symptoms varies considerably among patients. One cause for the differences in symptoms is the variable production of epinephrine and norepinephrine by these tumors. PHEOs that produce epinephrine tend to cause paroxysmal β-adrenergic manifestations, particularly anxiety, tremor, diaphoresis, tachycardia, palpitations, and hyperglycemia. Epinephrine and cytokine secretion can cause pulmonary edema and ARDS. PGLs do not secrete epinephrine but most secrete norepinephrine that causes hypertension. PGLs are more likely to metastasize.

Manifestations and their approximate incidence include hypertension (90%), headaches (80%), diaphoresis (70%), and palpitations or tachycardia (60%). Other common symptoms include episodic anxiety (60%), tremor (40%), abdominal or chest pain (35%), pallor (30%), and nausea or vomiting (30%). Hyperglycemia occurs in about 30% but is usually asymptomatic; diabetic ketoacidosis has been reported but is very rare. Patients may also experience fever (28%), fatigue (25%), flushing (18%), and dyspnea (15%). Change in bowel habits occurs frequently with either constipation (13%) or diarrhea (6%). Visual changes occur in 12% with either transient blurring or field loss during attacks; metastases to the orbit or skull base may directly impinge on the optic nerve (see Table 11–14).

Triggers for paroxysms: Episodic paroxysms may not recur for months or may recur many times daily. Each patient tends to have a different pattern of symptoms, with the frequency or severity of episodes usually increasing over time. Attacks can occur spontaneously or may occur with bladder catheterization, anesthesia, or surgery. Acute attacks may also be triggered by eating foods containing tyramine: aged cheeses, meats, fish, beer, wine, chocolate, or bananas. Hypertensive crises can also be triggered by certain drugs: radiocontrast media (especially ionic type), MAO inhibitors, tricyclic antidepressants, sympathomimetics, decongestants, glucagon, chemotherapy, glucocorticoids (prednisone, dexamethasone), ACTH, opiates, metoclopramide, nicotine, and cocaine. Phenothiazines have been reported to cause shock and pulmonary edema in patients with PHEO.

Paroxysms can be induced by seemingly benign activities such as bending, rolling over in bed, exertion, abdominal palpation, or micturition (with bladder paragangliomas). There is an amazing

TABLE 11–14 Clinical manifestations of pheochromocytoma and paraganglioma.

Blood pressure	Hypertension: severe or mild, paroxysmal or sustained; orthostasis; hypotension/shock; normotension
Vasospasm	Cyanosis, Raynaud syndrome, gangrene; severe radial artery vasospasm with thready pulse; falsely low blood pressure by radial artery transducer
Multisystem crisis	Severe hypertension/hypotension, fever, encephalopathy, ARDS, renal failure, hepatic failure, death
Cardiovascular	Palpitations, dysrhythmias, chest pain, acute coronary syndrome, cardiomyopathy, heart failure, cardiac paragangliomas
Gastrointestinal	Abdominal pain, nausea, vomiting, weight loss, intestinal ischemia; pancreatitis, cholecystitis, jaundice; rupture of abdominal aneurysm; constipation, toxic megacolon
Metabolic	Hyperglycemia/diabetes; lactic acidosis; fevers
Neurologic	Headache, paresthesias, numbness, dizziness, CVA, TIA, hemiplegia, hemianopsia, seizures, hemorrhagic stroke; skull metastases may impinge on brain structures, optic nerve, or other cranial nerves; spinal metastases may impinge on cord or nerve roots
Pulmonary	Dyspnea; hypoxia from ARDS
Psychiatric	Anxiety (attacks or constant); depression; chronic fatigue; psychosis
Renal	Renal insufficiency, nephrotic syndrome, malignant nephrosclerosis; large tumors often involve the kidneys and renal vessels
Skin	Apocrine sweating during paroxysms, drenching sweats as attack subsides; eczema; mottled cyanosis during paroxysm
Ectopic hormone production	ACTH (Cushing syndrome); VIP (Verner-Morrison syndrome); PTHrP (hypercalcemia)
Children	More commonly have sustained hypertension, diaphoresis, visual changes, polyuria/polydipsia, seizures, edematous or cyanotic hands; more commonly harbor germline mutations, multiple tumors, and paragangliomas
Women	More symptomatic than men: more frequent headache, weight loss, numbness, dizziness, tremor, anxiety, and fatigue
Pregnancy	Hypertension mimicking eclampsia; hypertensive multisystem crisis during vaginal delivery; postpartum shock or fever; high mortality
General laboratory	Leukocytosis, erythrocytosis, eosinophilia
Associated tumors	Renal cell carcinoma, hemangioblastoma, gastric sarcoma, pulmonary chondroma, pituitary adenoma, papillary thyroid cancer

inter-individual variability in the manifestations of PHEO/PGLs. Most patients have dramatic symptoms, but other patients with incidentally discovered secretory PHEOs are completely asymptomatic. Patients who develop PHEOs as part of MEN 2 or VHL disease are especially prone to be normotensive and asymptomatic.

Blood pressure: Hypertensive crisis is the quintessential manifestation of PHEO/PGL. Blood pressure that exceeds 200/120 mm Hg is an immediate threat to life, being associated with encephalopathy or stroke, cardiac ischemia or infarction, pulmonary edema, aortic dissection, rhabdomyolysis, lactic acidosis, and renal insufficiency.

Definition of hypertension: In adults, hypertension is considered to be present when blood pressure exceeds 140 mm Hg systolic or 90 mm Hg diastolic. In children, blood pressure increases with age, such that maximal normal ranges are age dependent; hypertension is considered to be present when blood pressure measurements exceed the following: younger than 6 months, 110/60 mm Hg; 3 years, 112/80 mm Hg; 5 years, 115/84 mm Hg; 10 years, 130/90 mm Hg; and 15 years, 138/90 mm Hg.

Presentation of hypertension: Hypertension is present in 90% of patients in whom a PHEO/PGL is diagnosed. Hypertension occurs primarily from the secretion of norepinephrine. Epinephrine secretion variably increases blood pressure. Also, PHEO/PGLs often secrete neuropeptide Y that is a potent vasoconstrictor.

Some tumors may grow so large that they impinge upon the renal artery, causing increased renin production and secondary renovascular hypertension. Blood pressure patterns vary among patients with PHEOs. Adults most commonly have sustained but variable hypertension, with severe hypertension during symptomatic episodes. Paroxysms of severe hypertension occur in about 50% of adults and in about 8% of children with PHEO. Other patients may be completely normotensive, may be normotensive between paroxysms, or may have stable sustained hypertension.

Hypertension can be mild or severe and resistant to treatment. Severe hypertension may be noted during induction of anesthesia for unrelated surgeries. Although hypertension usually accompanies paroxysmal symptoms and may be elicited by the earlier activities, this is not always the case.

Orthostasis: Patients with sustained hypertension frequently exhibit orthostatic changes in blood pressure, often with orthostatic tachycardia. Patients may complain of orthostatic faintness. Blood pressure may drop, even to hypotensive levels, after the patient arises from a supine position and stands for 3 minutes; such orthostasis, especially when accompanied by a rise in heart rate, is suggestive of PHEO. Epinephrine secretion from a PHEO may cause episodic hypotension and even syncope.

Hypotension and shock: Although hypertension is usually the key symptom in PHEO/PGL patients, hypotension and shock can occur. Some PHEOs produce purely epinephrine that can

produce mild hypertension from alpha stimulation but can also produce hypotension from predominantly β-stimulated vasodilation. After an especially intense and prolonged attack of hypertension, shock may ultimately occur. This may be due to loss of vascular tone, low plasma volume, arrhythmias, or cardiac damage. Spontaneous necrosis within a PHEO can lead to severe hypotension when norepinephrine levels suddenly drop. Similarly, surgical resection of a PHEO/PGL often precipitates sudden and severe intraoperative hypotension, particularly in the presence of α-blockade and other antihypertensives. Cardiogenic shock can occur as a result of cardiac ischemia or infarction as well as catecholamine cardiomyopathy (see Cardiac Manifestations, discussed later).

Peripheral vasospasm and gangrene: Vasoconstriction is responsible for the pallor and mottled cyanosis that can occur with paroxysms of hypertension. Raynaud phenomenon can occur. Peripheral pulses may become thready or even nonpalpable during paroxysms. Catheters inserted into the radial artery and connected to continuous blood pressure monitoring transducers can give misleadingly low-pressure readings during paroxysms of vasospasm, a condition known as **pseudoshock**. Prolonged severe peripheral vasospasm has rarely caused gangrene of the skin, fingers, or toes. Reflex vasodilation usually follows an attack and can cause facial flushing.

Multisystem crisis: Massive release of catecholamines and cytokines from PHEO/PGL tumors can occur spontaneously during tumor necrosis or can be triggered by any of the factors noted earlier. This can cause multisystem crisis that can be the presenting manifestation of PHEO/PGL, with hypertension or hypotension, high fever, encephalopathy, cardiomyopathy with heart failure, ARDS, renal failure, hepatic injury, and death. Multisystem crisis resembles septic shock, so the diagnosis of PHEO may be missed entirely.

Cardiac manifestations: The heart is affected in most patients with PHEO/PGL, either directly from excessive catecholamines or indirectly from hypertension. Palpitations are one of the most frequent complaints.

Dysrhythmias: Tachycardia or dysrhythmias occur in about 60% of patients with PHEO/PGL. Patients may note palpitations, described variably as episodes of excessive heart pounding at rest or a fluttering sensation, during which they may become lightheaded. Supraventricular tachycardia is common, particularly in patients with an epinephrine-secreting adrenal PHEO. The heart rate will often increase when standing. There can be an initial tachycardia during a paroxysm, followed by a reflex bradycardia. Atrial fibrillation may occur. Other dysrhythmias described with PHEO/PGL include nodal tachycardia, torsades de pointes, sick sinus syndrome, and Wolff-Parkinson-White (WPW) syndrome. Atrioventricular dissociation can occur and right bundle branch block has been reported. Ventricular tachycardia or ventricular fibrillation can occur suddenly and is a common cause of death.

Acute coronary syndrome (ACS): During a paroxysm, severe coronary vasospasm can cause myocardial ischemia or infarction, even in the absence of coronary atherosclerosis. This typically occurs simultaneously with increased myocardial oxygen demand caused by catecholamine-induced increases in heart rate and contractility. Patients may experience crushing chest pain or pressure with referred pain, usually to the jaw or the left shoulder or arm. Acute heart failure may occur along with severe hypotension or shock.

It can be difficult to distinguish ACS due to coronary stenosis/thrombosis from ACS due to a PHEO. Changes in the electrocardiogram and serum levels of troponin and creatine kinase-MB (CK-MB) are the same for both conditions. Patients with coronary disease can have tachycardia, cardiomyopathy, hypertension, dysrhythmias, diaphoresis, anxiety, and increased plasma catecholamine levels. However, patients with PHEO usually do not have critical coronary artery stenosis on coronary angiogram and usually have severe hypertension, headache, and other paroxysmal symptoms.

Cardiomyopathy: Left ventricular hypertrophy and hypertensive cardiomyopathy can occur in patients with chronic hypertension from a PHEO/PGL. High levels of catecholamines can also directly cause myocarditis and a dilated cardiomyopathy. This is known as **catecholamine cardiomyopathy**. Takotsubo cardiomyopathy is the term used to describe asymmetric cardiac contractility with apical and midventricular akinesis or dyskinesis with hyperkinesis at the base. Other patterns of cardiac hypokinesis can occur. Most patients with catecholamine cardiomyopathy develop pulmonary edema and die. However, full recovery from cardiomyopathy may occur after treatment and surgical resection of a PHEO/PGL. In some patients, myocardial scarring and fibrosis lead to irreversible cardiomyopathy and heart failure. Fatal Takotsubo cardiomyopathy has been reported after dobutamine stress echocardiography.

There can be multiple causes of cardiomyopathy in patients with PHEO/PGL: hypertensive, ischemic, and catecholamine. The underlying pathophysiology of catecholamine cardiomyopathy appears to involve high levels of intracellular calcium in cardiac myocytes. Postmortem histopathology typically reveals intracardiac hemorrhages, edema, and concentrations of lymphocytes and leukocytes in cardiac muscle with areas of myocardial fibrosis.

Cardiac PGLs: These are rare tumors that arise at the base of the heart near the trunks of the aortic and pulmonary arteries and may be asymptomatic or cause hypertension and palpitations. They typically involve the left atrium or interatrial groove and often protrude into the atrium, resembling an atrial myxoma. Cardiac PGLs often have an invasive intramural component, making tumor resection difficult.

Diaphoresis and fever: During a paroxysm, sweating usually occurs initially from apocrine glands, affecting the palms, axillae, head, and shoulders. Reflex thermoregulatory eccrine sweating occurs later in an attack, dissipating the heat that was acquired during the prolonged vasoconstriction that occurred during the paroxysm. This can cause drenching sweats, usually as a paroxysm subsides. Patients with PHEO commonly develop fevers that may be mild or severe, even as high as 41°C. Up to 70% of patients have unexplained low-grade elevations in temperature of 0.5°C or more. Such fevers have been attributed to the secretion of interleukin-6 and respond to nonsteroidal anti-inflammatory drug therapy.

Gastrointestinal manifestations: Many patients with PHEO/PGL exhibit gastrointestinal symptoms such as abdominal pain, nausea, vomiting, and constipation. Most patients lose some weight, even if appetite is preserved. More severe weight loss (>10% of basal weight) occurs in about 15% of patients overall and in 41% of those with sustained and prolonged hypertension. Abdominal pain may be due to splanchnic vasoconstriction (*intestinal angina*) and prolonged vasospasm can cause ischemic enterocolitis. Vasospasm can rarely cause ischemic gangrene of the bowel. Pain may also be caused by the growth of a large intra-abdominal tumor. Intestinal motility disorders are also common. Catecholamines relax gastrointestinal smooth muscle while increasing contraction of the pyloric and ileocecal sphincters. Constipation is common, and abdominal distention and even toxic megacolon can occur. Other abdominal emergencies can be seen with PHEO, including the rupture of an aortic aneurysm, acute cholecystitis, and acute pancreatitis.

Neurologic manifestations: Headache is a common manifestation during an acute paroxysm. Patients frequently complain of paresthesia, numbness, or dizziness. Affected patients have an increase risk of experiencing a cerebrovascular accident (CVA) or transient ischemic attack (TIA). Hemiplegia can occur, sometimes with homonymous hemianopsia, and may be transient or permanent. Although most CVAs are ischemic in origin, hemorrhagic stroke can also occur during hypertensive paroxysms. Rupture of the internal carotid artery into the cavernous sinus can occur, causing a third nerve palsy. Some patients develop confusion or even psychosis during paroxysms. Paresthesias can occur.

Pulmonary manifestations: Patients may complain of dyspnea during a paroxysm. Patients with catecholamine cardiomyopathy may also present with dyspnea. Some patients develop ARDS, which can develop acutely or over several days. This is a life-threatening condition but may be self-limited during an attack. PHEO/PGL can produce ARDS that may be mistaken for pneumonia, pulmonary edema, pulmonary emboli, or congestive heart failure. It is hypothesized that ARDS may be caused by interleukin-6 produced by the tumor. Congestive heart failure may also cause pulmonary edema and can be distinguished from ARDS by echocardiogram.

Renal manifestations: Some degree of renal insufficiency is common in patients with PHEO. Hypertensive nephrosclerosis occurs in patients with a long history of severe hypertension. Nephrotic syndrome may occur with significant proteinuria, possibly due to secretion of interleukin-6 by the tumor. Malignant nephrosclerosis can occur with severe hypertension damaging renal arterioles, resulting in rapidly progressive renal failure. Large PHEOs and perirenal PGLs can impinge upon the renal artery, causing increased renin production and a Goldblatt kidney, resulting in renovascular hypertension that is additive to norepinephrine-induced hypertension. The tumor may directly invade the renal vein and extend into the inferior vena cava, causing pulmonary emboli and an increased risk of lower extremity deep vein thrombosis. Severe hypertensive paroxysms can cause muscle ischemic damage and rhabdomyolysis with release of myoglobin that causes myoglobinuric renal failure. Acute tubular necrosis can occur after a severe hypotensive episode.

Ectopic hormone production: PHEOs can rarely produce ACTH that stimulates the adrenal cortex to produce excessive cortisol, resulting in Cushing syndrome. Tumors can also produce VIP that can cause watery diarrhea, hypokalemia, and achlorhydria, the WHDA (Verner-Morrison) syndrome. Some tumors produce PTHrP that causes hypercalcemia. Although PHEOs can secrete renin directly, elevated plasma renin levels are usually derived from the juxtaglomerular apparatus, whose β_1 receptors are stimulated by both epinephrine and norepinephrine.

Manifestations in children: The symptoms of PHEO/PGL in children are different from those in adults. Over 80% of children exhibit hypertension that is usually sustained and less frequently (10%) paroxysmal. Children are more prone to diaphoresis and visual changes. Children are more likely to have paroxysms of nausea, vomiting, and headache, which often occur after exertion. They are also prone to weight loss, polydipsia, polyuria, and convulsions. Affected children may also exhibit reddish-blue mottled skin along with edematous and cyanotic-appearing hands, a symptom rarely seen in adults. Children are more likely to have multiple tumors and extra-adrenal PGLs. In one series, 39% of affected children had bilateral adrenal PHEOs, an adrenal PHEO plus a PGL, or multiple PGLs; a single PGL occurred in an additional 14% of children. Affected children often have genetic conditions associated with PHEOs/PGLs. Thus, they may harbor the other tumors associated with these conditions. All affected children should be considered for genetic testing for germline mutations or deletions predisposing to PHEO/PGL (see Table 11–8).

Manifestations in women: There are sex differences in PHEO/PGL symptomatology, with women tending to be more symptomatic than men. Women report significantly more headache (80% vs 52%), weight change (88% vs 43%), numbness (57% vs 24%), dizziness (83% vs 39%), tremor (64% vs 33%), anxiety (85% vs 50%), and changes in energy level (89% vs 64%).

Manifestations in pregnancy: A PHEO/PGL during pregnancy can cause sustained hypertension or paroxysmal hypertension that is typically mistaken for eclampsia. Hypertensive paroxysms tend to occur more frequently as the uterus enlarges, triggered by direct pressure upon the tumor by shifts in position or movement of the fetus. Hypertensive crisis typically occurs at the time of vaginal delivery and is commonly associated with cardiac arrhythmia, ARDS, and death. Postpartum women may develop shock or fever that can mimic uterine rupture, amniotic fluid embolus, or infection (puerperal sepsis). A tumor that is unrecognized carries a grave prognosis, with a reported 40% maternal mortality and a 56% fetal mortality. If the diagnosis of PHEO is made before delivery, the maternal mortality rate drops to about 10% (see Pregnancy and Pheochromocytoma, discussed later).

Manifestations of malignancy: Metastases occur in about 11% of adrenal PHEOs and 30% to 50% of sympathetic PGLs. Since histopathology cannot distinguish whether a given PHEO is malignant, the term malignant is dependent upon whether metastases are detectable at presentation (50%) or months to years later (50%). Metastases are usually (80%) functional and can cause recurrent hypertension and symptoms many months or years after an operation that had been thought to be curative (see Metastatic Pheochromocytoma and Paraganglioma, discussed later).

Normotension despite high plasma levels of norepinephrine: Interestingly, about 14% of patients with PHEO/PGL have no hypertension despite having chronically elevated serum norepinephrine levels. This phenomenon has been variably called desensitization, tolerance, or tachyphylaxis.

Patients can be genetically prone to adrenergic desensitization. Adrenergic desensitization is caused by adrenergic receptors undergoing sequestration, down-regulation, or phosphorylation. Adrenergic desensitization appears to be one cause of the cardiovascular collapse that can occur abruptly following the surgical removal of a PHEO/PGL in some patients.

Desensitization does not account for all patients who are normotensive in the face of elevated serum levels of norepinephrine, because some such patients can still have hypertensive responses to norepinephrine. Secretion of epinephrine can have a hypotensive effect and may account, at least in part, for this phenomenon. Some patients are homozygous for certain polymorphisms of β_2-adrenergic receptors that allow continued β_2-adrenergic-mediated vasodilation, thus counteracting the pressor effects of circulating epinephrine and norepinephrine caused by stimulation of vascular α_1-adrenergic receptors.

Cosecretion of dopamine may reduce blood pressure through a central nervous system action. Also, cosecretion of dopamine may directly dilate mesenteric and renal vessels and thus modulate the effects of norepinephrine.

Biochemical Testing for Pheochromocytoma

No single test is absolutely sensitive and specific for PHEO. Plasma-fractionated free metanephrines or urinary 24-hour fractionated metanephrines have a sensitivity of about 97%. Sensitivities of other tests are somewhat lower: urinary norepinephrine 93%, plasma norepinephrine 92%, urinary VMA 90%, plasma epinephrine 67%, urinary epinephrine 64%, and plasma dopamine 63%. However, some malignant tumors secrete only dopamine and no catecholamines and no metanephrines at all. Also, the determination of plasma catecholamines-metanephrine ratios can be of value in discriminating false-positive from true-positive results (discussed later). Therefore, assays for plasma catecholamines, dopamine, and serum chromogranin A are often warranted.

PHEO/PGLs are deadly tumors and missing the diagnosis can be disastrous, so screening tests must be very sensitive. The secretion of catecholamines can be paroxysmal, with low secretion rates between paroxysms. In contrast, the secretion of metanephrine or normetanephrine metabolites is relatively high and constant. Tumors secrete metanephrines in their unconjugated (free) form. Thus, plasma-fractionated free metanephrines is the single most sensitive screening tests for these tumors. Urinary 24-hour fractionated metanephrines has a similar sensitivity but the collection is less convenient. Some rare tumors (usually malignant) have a defect in the conversion of dopamine to norepinephrine by DBH, such that serum dopamine levels are very high while catecholamines are normal or mildly elevated and metanephrines are totally normal. Additionally, some paragangliomas secrete no catecholamines or metanephrines but do secrete CgA.

The establishment of normal reference ranges is problematic for catecholamines and metanephrines, since levels vary with sex, age, and medical conditions:

1. **Sex** Women have lower plasma epinephrine and metanephrine levels than men; their urinary excretion of catecholamines and metanephrines is also lower. Women also have lower 24-hour urine metanephrine and normetanephrine than do men. However, such sex differences disappear when normalized to creatinine excretion.
2. **Age** Children, especially boys, normally have somewhat higher levels of plasma epinephrine and metanephrine than do adults. For boys ages 5 to 17 years, the upper limit of normal (ULN) for plasma free metanephrine is less than 57 pg/mL (0.52 nmol/L) and the ULN for plasma free normetanephrine is 97 pg/mL (0.53 nmol/L). For girls ages 5 to 17 years, the ULN for plasma free metanephrine is 0.37 nmol/L and the ULN for plasma free normetanephrine is 77 pg/mL (0.42 pmol/L). Conversely, children's average 24-hour urine epinephrine and norepinephrine excretion rates are lower than those of adults and increase through childhood as weight increases. Therefore, using ratios of catecholamines to creatinine and metanephrines to creatinine best assesses children's 24-hour urine tests.

   Commonly, the adult plasma free metanephrine ULN is reported to be 57 pg/mL (0.31 nmol/L), with the adult plasma free normetanephrine ULN reported to be 148 pg/mL (0.75 nmol/L). However, reference ranges vary greatly between laboratories. The reported ULN for plasma free metanephrine ranges from 55 pg/mL to 85.6 pg/mL (0.30-0.47 nmol/L), and the reported ULN for plasma free normetanephrine ranges from 110 to 200 pg/mL (0.56-1.02 nmol/L). Plasma norepinephrine and normetanephrine levels increase with advancing age. For patients over age 65, the plasma-fractionated free normetanephrine ULN should be considered 200 pg/mL (1.02 nmol/L).
3. **Medical conditions** On average, hospitalized patients and those with essential hypertension have higher levels of catecholamines and metanephrines (plasma and urine) than do matched nonhospitalized and normotensive individuals. Therefore, many laboratories have separate reference ranges for hypertensives and nonhypertensives.

Patients with illness, trauma, or sleep apnea have increased excretion of both catecholamines and metanephrines. Patients with renal failure on dialysis have elevated levels of plasma catecholamines (58%), plasma free metanephrines (25%), and plasma total (deconjugated) metanephrines (100%). Patients with partial renal insufficiency also have misleadingly elevated levels of plasma catecholamines (32%), plasma free metanephrines (26%), and plasma total metanephrines (50%). Thus, in patients with renal failure, the best screening test is plasma free metanephrines, but the test still lacks specificity when elevated. Serum CgA levels are also elevated in renal insufficiency.

Misleading elevations of at least one metanephrine or catecholamine determination occur in 10% to 20% of tested individuals without PHEO/PGL. These elevations are typically less than 50% above the maximum normal and often normalize on retesting. Patients with PHEOs usually have elevations of metanephrines or catecholamines that are more than three times normal. In one large series, a false-positive elevation in at least one test occurred

in 22% and marked elevations in at least one test occurred in 3.5% of patients with no PHEO. False-positive test results were judged to have occurred from physiologic variation (33%), laboratory errors (29%), or drug interference (21%).

Plasma normetanephrines reflect disease activity in patients with secretory PGLs or metastases. Normal ranges for plasma metanephrines in children are different from those of adults and have been reported by Weise et al, 2002. Plasma normetanephrine levels typically increase with age; about 16% of older patients being evaluated for PHEO/PGL have levels above the published normal range for young adults (false positives); only 3% of young adults have false-positive plasma normetanephrine concentrations. Stimulation tests are not recommended (discussed later).

A. Metanephrines and catecholamines

Plasma-fractionated free metanephrines The most sensitive and simple screening test for PHEO/PGL is an assay for plasma-fractionated (metanephrine and normetanephrine) free metanephrines. This assay is particularly useful to screen patients for secretory PHEO/PGL (see Table 11–7). For younger children, plasma testing is particularly preferred over urine testing due to the relative ease of collection. This assay's sensitivity pertains to secretory PHEO/PGL. However, some tumors, particularly PGLs, may not secrete any metanephrines. So to screen for a PGL in a normotensive patient with a suspicious mass, it is recommended that plasma dopamine and serum CgA also be tested, since some PGLs secrete purely dopamine or only CgA (discussed later).

In the United States, most reference laboratory assays for metanephrines employ high-pressure liquid chromatography (HPLC) with tandem mass spectrometry (MS/MS). This test is 97% sensitive. The 3% of affected patients with PHEO/PGL with normal plasma-fractionated free metanephrines usually have very small tumors, nonsecreting tumors, or dopamine-secreting tumors such that they are not hypertensive. Although MS/MS reduces drug interference that can be a problem with assays that employ HPLC with electrochemical detection (ECD), the test is only 87% specific for PHEO/PGL in a referred patient population.

Patient preparation: In order to reduce the chance of false-positive testing, patients having plasma-fractionated free metanephrines determinations by tandem mass spectroscopy (MS/MS) should observe the following precautions: No decongestants, amphetamines, MAO inhibitors, or cocaine for at least 7 days before testing. The patient must not have any current stressful illness or be in withdrawal from alcohol, narcotics, or clonidine. There must be full recovery from any postoperative pain. The patient should have no local anesthetics (lidocaine) or acetaminophen for 24 hours before blood draw. Overnight fasting is preferred (water permitted). Patients should avoid coffee (including decaffeinated coffee) tea, tobacco, and strenuous exercise on the day of the blood draw. The patients being screened should be relaxed and ideally resting supine for at least 15 minutes prior to the blood draw; if that is not possible in an outpatient laboratory, the patient should at least sit quietly for a minimum of 15 minutes before the blood draw.

Since the test's specificity is much lower than its sensitivity, most patients with levels above the reference range do not harbor

a tumor. This is particularly true when plasma levels are less than three times higher than the upper limit of the reference range. Conversely, it is extremely likely that a patient harbors a PHEO when the plasma free metanephrine is above 220 pg/mL (1.2 nmol/L) or the plasma free normetanephrine is above 430 pg/mL (2.2 nmol/L). Patients with abnormally high plasma-fractionated metanephrines usually need to have the test repeated under controlled conditions (see Patient Preparation, discussed earlier), along with a 24-hour urine collection for fractionated metanephrines, catecholamines, and creatinine (discussed later).

Normally, about 90% of circulating metanephrine and about 50% of circulating normetanephrine originate directly from the adrenal medulla. The term **total metanephrines** refers to both normetanephrine and metanephrine. There are two circulating forms of normetanephrine and metanephrines: free and sulfate-conjugated metanephrines. The free metanephrines produced in the adrenal medulla and paraganglia are sulfate-conjugated by intestinal tissue; the sulfated form represents 97% of circulating metanephrines. Only 3% of total circulating metanephrine is free. Plasma metanephrine levels are sometimes measured after a deconjugation step, such that both free and conjugated metanephrines are measured; this assay is termed **deconjugated metanephrines** and reflects mostly the sulfate-conjugated species. The plasma free metanephrines assay is superior to the total (deconjugated) metanephrine assay.

The sensitivity of the plasma free metanephrines is due to the tumor's continuous secretion of metanephrines. Catecholamines in secretory vesicles exist in a dynamic equilibrium with the surrounding cytoplasm, with catecholamine uptake into the vesicles being balanced by their leakage into the cytoplasm. In the cytoplasm, the enzyme COMT converts epinephrine to metanephrine and converts norepinephrine to normetanephrine. The catecholamine metabolites then leak out of the cell continuously to become free metanephrines. While catecholamines are secreted in bursts associated with exocytosis of neurosecretory vesicles, free metanephrines are produced continuously. This eliminates the need to catch a paroxysmal hypertensive event. Plasma free metanephrine levels are within the reference range in 75% of patients on dialysis and 74% of patients with renal insufficiency. In contrast, plasma deconjugated metanephrines are within the reference range in 0% of patients on dialysis and in 50% of patients with renal insufficiency.

Factors causing misleading plasma free fractionated metanephrine levels (Table 11–15) *Smoking* can elevate plasma free metanephrine assays. The patient must not smoke for at least 4 hours before collection. *Coffee* increases plasma normetanephrine by 20% and *food consumption* increases it by 8%; but they have no effect upon plasma metanephrine levels. *Sympathomimetics* such as decongestants and amphetamine derivatives should be discontinued for at least 7 days before the test. Other drugs that can misleading elevate plasma free metanephrines include *local anesthetics, cocaine, lidocaine, halothane anesthesia, and MAO inhibitors. Acetaminophen is one of the few medications that can actually interfere with the MS/MS assay.* Conditions that increase plasma metanephrine and normetanephrine levels include

any *severe physical stress such as acute illness or narcotic or alcohol withdrawal, anxiety, sleep apnea, renal failure, and essential hypertension. Physical exercise* raises plasma free metanephrine and normetanephrine by over 80%. There can be seasonal variations in plasma normetanephrine levels, with 20% higher levels during *winter* being reported in Germany and the Netherlands.

Assumption of a supine resting position reduces plasma metanephrine by an average of 34% and reduces normetanephrine by 19%, compared to standing at rest. Blood samples should ideally be drawn from an indwelling heparin-locked intravenous line while the patient is fasting and resting supine. However, it is not usually practical for patients to rest supine for prolonged periods in outpatient laboratories, so patients are advised to sit quietly for at least 15 minutes prior to the blood draw. Blood should be centrifuged immediately and stored at 4°C to improve stability.

In patients with adrenal PHEO, over 90% of circulating metanephrine originates from the tumor, while variable percentages of circulating normetanephrine originate from the tumor. Patients with elevated plasma metanephrine or epinephrine are likely to have an adrenal PHEO, since PGLs do not ordinarily secrete epinephrine or metanephrine. Metastases from epinephrine-secreting adrenal PHEOs may sometimes continue to secrete epinephrine and its metabolite metanephrine.

24-Hour urine-fractionated metanephrines

This assay, which measures the sum of both conjugated and free urinary metanephrines, rivals plasma free metanephrines in sensitivity. In the United States, most reference laboratories employ tandem mass spectrometry (MS/MS), which eliminates interference from most drugs and foods. Urinary metanephrines are rather stable compounds, so it is not necessary to collect the specimen with acid preservative. Conversely, acid preservative (used for collection of urinary catecholamines) does not adversely affect metanephrines. Urine fractionated 24-hour metanephrines are useful to confirm high plasma levels or to help rule-out a PHEO/PGL in patients with marginal elevations in plasma-fractionated metanephrines. The disadvantages of 24-hour urine collections include: (1) the inconvenience to the patient; (2) the likelihood that there will be an error in the patient's collection or in the laboratory's handling of the specimen; (3) the lower specificity for urinary fractionated metanephrines (69%) compared to plasma-fractionated free metanephrines (89%); (4) the inaccuracy for patients with renal failure (see Appendix for normal reference ranges for 24-hour metanephrines).

Like plasma-fractionated metanephrines, urinary metanephrines are much more sensitive than they are specific. Most patients with elevated levels of fractionated metanephrines do not harbor a PHEO if their levels are less than three times the upper limit of the reference range. Conversely, patients are very likely to have a pheochromocytoma if the 24-hour urine metanephrine excretion is above 600 μg/d (3.0 μmol/d) or normetanephrine excretion is above 1500 μg/d (8.2 μmol/d).

As with plasma metanephrines, patients with a definitely elevated urinary metanephrine are likely to harbor an adrenal PHEO, since PGLs rarely secrete epinephrine or metanephrine.

Plasma-fractionated catecholamines

Misleading elevations in plasma catecholamines commonly occur from the stress of having the phlebotomy. Normal plasma levels of catecholamines are listed in the Appendix. In patients with PHEO/PGL, plasma concentrations of norepinephrine do not correlate well with blood pressure.

Although plasma metanephrines are more sensitive than plasma catecholamines for detecting a PHEO, plasma catecholamines are of value in helping distinguish true-positive from false-positive results. In normal individuals, about 100% of circulating epinephrine originates from the adrenal medulla, while over 90% of circulating norepinephrine originates from peripheral sympathetic synapses. In both normals and those with PHEOs, plasma norepinephrine levels fluctuate with the degree of peripheral sympathetic activation and both epinephrine and norepinephrine levels can increase during PHEO paroxysms. In patients with PHEOs, the tumor's production of metanephrine metabolites is rather constant and relatively unrelated to peripheral sympathetic activity or a tumor's paroxysmal catecholamine secretion. Patients with false-positive test results due to sympathetic activation tend to have the following pattern: a higher percentage increase of plasma norepinephrine above the upper limit of the reference range compared to plasma normetanephrine; a higher percentage increase of plasma epinephrine above the upper limit of the reference range compared to plasma metanephrine. Plasma dopamine should be assayed in normotensive patients with a mass that is suspicious for a PGL, since some PGLs secrete only dopamine.

Plasma catecholamines are of limited value in patients on dialysis and in those with renal insufficiency. About 58% of dialysis patients have plasma catecholamines above the normal reference range; about 32% of renal insufficiency patients have catecholamines above the normal reference range.

Most assays for plasma catecholamines currently employ HPLC with ECD; assays using tandem mass spectrometry (MS/MS) have not become generally available.

Urine-fractionated catecholamines and dopamine

Adult normal maximal urinary concentrations for catecholamines and their metabolites are listed in the *Appendix*. A single 24-hour urine specimen is collected for fractionated catecholamines, fractionated metanephrines, dopamine, and creatinine. The container is acidified with 10 to 25 mL of 6 N HCl for preservation of the catecholamines; the acid does not interfere with metanephrine and creatinine assays. The acid preservative may be omitted for children for safety reasons, in which case the specimen should be kept cold and processed immediately. The laboratory requisition form should request that assays for fractionated catecholamines, fractionated metanephrines, and creatinine be performed on the same specimen. Urinary dopamine determination is not a sensitive test for PHEOs. However, in patients with established PHEOs, a normal urine dopamine is fairly predictive of benignity, whereas elevated urine dopamine excretion is seen in both benign and malignant PHEOs.

Single-void (spot) urine specimens

can be collected on first morning void or following a paroxysm. No acid preservative is used on single-void specimens, because it dilutes the specimen and

is not required. For single-void collections, patients are instructed to void and discard the urine immediately at the onset of a paroxysm and then collect the next voided urine. The laboratory requisition should request spot urine for total metanephrines and creatinine concentrations. It is prudent to contact the laboratory directly and explain that the specimen is meant to be a single-void urine and not a 24-hour specimen, else the specimen may be rejected. Patients with PHEOs generally excrete over 2.2 μg total metanephrine/mg creatinine.

B. Serum CgA   Some tumors (mostly PGLs) fail to secrete catecholamines or metanephrines. Serum CgA is a useful test to diagnose and monitor such nonsecretory tumors. CgA may be determined by immunoradiometric assays. The serum CgA assay has become useful for the diagnosis of PHEO. However, CgA undergoes extensive tumor-specific cleavages so that only certain serum assays are useful for clinical diagnosis.

Serum CgA levels have a circadian rhythm in normal individuals, with lowest levels found at 8 AM and higher levels in the afternoon and at 11 PM. CgA levels are not elevated in essential hypertension. CgA is also secreted from extra-adrenal sympathetic nerves. Serum CgA levels are elevated in the great majority of patients with PHEOs. The serum levels of CgA correlate with tumor mass, making CgA a useful tumor marker. However, smaller tumors may not be diagnosed. Serum CgA levels tend to be particularly elevated in patients with metastatic PHEO.

Serum CgA can be elevated even in patients with biochemically silent tumors. In patients with normal renal function, serum CgA has a sensitivity of 83% to 90% and a specificity of 96% for diagnosis of these tumors. However, the usefulness of serum CgA levels is negated by any degree of renal failure because of its excretion by the kidneys; even mild azotemia causes serum levels to be elevated. However, in patients with normal renal function, a high serum level of CgA along with high urine or plasma catecholamines or metanephrines is virtually diagnostic of PHEO.

Since CgA is also cosecreted with gastrin, serum CgA levels are also elevated in conditions with elevated serum gastrin: atrophic gastritis, pernicious anemia, postvagotomy, gastrinoma, gastric carcinoma, carcinoid tumor, and small cell lung carcinoma. CgA levels are elevated in about 60% of patients taking proton pump inhibitors (PPIs), but not H_2 blockers. Serum CgA levels rise variably after meals, so blood for CgA should be drawn after an overnight fast or repeated fasting if a nonfasting level is elevated. False-positive testing has also occurred in patients with inflammatory bowel disease, liver disease, hepatocellular carcinoma, prostate cancer, pituitary tumors, rheumatoid arthritis, and stress. False-positives have been reported to be due to heterophile antibody interference with the assay. Serum CgA levels can also be elevated without any discernable cause.

C. Suppression and stimulation testing   Glucagon stimulation testing is no longer used since it can cause dangerous hypertension.

Clonidine suppression test: This test may help distinguish patients with PHEO from normals with elevated normetanephrine levels. Clonidine is a central α_2 adrenergic blocker that suppresses the release of norepinephrine at sympathetic nerve synapses, thereby reducing circulating levels of norepinephrine and its metabolite, normetanephrine. In contrast, in patients with PHEO, most circulating normetanephrine is derived from continuous leakage from the tumor, such that clonidine is less able to suppress it. This test is most accurate when free normetanephrine is assayed, rather than norepinephrine.

To perform the clonidine suppression test, the patient must be fasting overnight and avoid smoking or interfering medications such as phenoxybenzamine, β-adrenergic blockers, tricyclic antidepressants and diuretics for at least 48 hours. An indwelling venous catheter is inserted, and the patient should remain recumbent. Thirty minutes later, blood is drawn for baseline plasma free normetanephrine. Clonidine is then given orally in a dose of 0.3 mg/kg; 3 hours afterward, blood is again drawn for plasma free normetanephrine.

In a study of 49 normals without PHEO, clonidine suppressed plasma normetanephrine levels more than 40% or to below 112 pg/mL in 100%. However, clonidine failed to suppress normetanephrine in 46 of 48 patients with PHEO. Despite the potential helpfulness of the clonidine suppression test, it cannot be completely relied upon. Unnecessary surgeries have been performed on the basis of misleading clonidine suppression testing.

D. Other laboratory tests

1. **Urine VMA** Urinary VMA determinations have an overall diagnostic sensitivity for PHEO of only about 63% and do not improve the sensitivity or specificity of other tests for the diagnosis of PHEO. However, some centers have traditionally used a combination of 24-hour urinary VMA, metanephrine, and creatinine determinations with good results. VMA is stable for 5 days at room temperature; 6 N HCl is used to preserve urine specimens that are stored for longer than 5 days before analysis. Before urine collections for VMA testing, patients must avoid salicylates, caffeine, phenothiazines, and antihypertensive drugs for 72 hours. Coffee, tea, chocolate, bananas, and vanilla must also be avoided. Normal ranges for VMA vary by age (see Appendix).

2. **Plasma renin activity** Levels of plasma renin activity are not typically suppressed in patients with PHEO/PGL because catecholamines stimulate renin release, and some tumors may secrete renin ectopically.

3. **Other tests** Patients with PHEO/PGL are frequently found to have an increased white blood count with a high absolute neutrophil count. Counts as high as 23,600/μL have been reported. Marked eosinophilia may sometimes occur. Hyperglycemia is noted in about 35% of patients with PHEO, but frank diabetes mellitus is uncommon. The erythrocyte sedimentation rate is elevated in some patients. Hypercalcemia is common and may be caused by bone metastases or tumoral secretion of PTHrP. Hypocalcemia occurs rarely. Erythrocytosis sometimes occurs, usually due to volume contraction and rarely due to ectopic secretion of erythropoietin.

Factors That May Cause Misleading Biochemical Testing for PHEO (Table 11–15)

Several different methods may be employed for assay of urine and plasma catecholamines and metanephrines. Each assay uses different

TABLE 11–15 Factors that can cause misleading catecholamine or metanephrine results.[a]

Drugs	Foods	Conditions
Acetaminophen[b]	Bananas[c]	Age (children & elderly)[f]

methods and internal standards. Most assays for catecholamines now employ HPLC with ECD. Such assays can be affected by interference from a diverse range of drugs and foods. These substances cause unusual shapes in the peaks on the chromatogram. Not all of these assays are the same, and the potential for interference depends on the particular method employed. Therefore, it is best to check with the reference laboratory that runs the test or provides the test kit.

A. Drugs   Certain radiopaque contrast media, including those that contain meglumine acetrizoate or meglumine diatrizoate (eg, Renografin, Hypaque-M, Renovist, Cardiografin, Urografin, and Conray), can falsely lower urinary metanephrine determinations in some assays for up to 12 hours following administration. However, diatrizoate sodium is an intravenous contrast agent that does not cause such interference and should be requested if a CT scan must be performed prior to testing for metanephrines. Many other drugs cause interference in the older fluorometric assays for VMA and metanephrines. Tandem mass spectrometry for metanephrines virtually eliminates direct drug interference in the assay.

B. Foods   Even while using HPLC-ECD assay techniques, certain foods can cause misleading results in assays for catecholamines and metanephrines (see Table 11–15). Coffee (even if decaffeinated) contains substances that can be converted into a catechol metabolite (dihydrocaffeic acid) that may cause confusing peaks on HPLC. Caffeine inhibits the action of adenosine; one action of adenosine is to inhibit the release of catecholamines. Heavy caffeine consumption causes a persistent elevation in norepinephrine production and raises blood pressure an average of 4 mm Hg systolic. Bananas contain considerable amounts of tyrosine, which can be converted to dopamine by the central nervous system; dopamine is then converted to epinephrine and norepinephrine. Dietary peppers contain 3-methoxy-4-hydroxybenzylamine (MHBA), a compound that can interfere with the internal standard used in some assays for metanephrines.

C. Diseases   Any severe stress can elicit increased production of catecholamines and metanephrines. Urinary excretion of catecholamines and metanephrines is reduced in renal failure.

Differential Diagnosis of Pheochromocytoma and Paraganglioma (Table 11–16)

PHEOs and PGLs have such protean manifestations that many conditions enter into the differential diagnosis. Essential hypertension is extremely common, and it is not practical to screen for PHEO in all patients with elevated blood pressure. However, PHEO should enter the differential diagnosis for any hypertensive patient having blood pressures above 180 mm Hg systolic and for any hypertensive patient who has one of the following symptoms: headaches, palpitations, sweating episodes, or unexplained bouts of abdominal or chest pains.

Anxiety (panic) attacks begin abruptly and can be associated with tachycardia, tachypnea, and chest discomfort, symptoms that are commonly seen with PHEOs. However, patients with panic attacks are more likely to have a precipitating social situation, tend to be exhausted for more than 2 hours following an attack, live in dread of the next attack, and often change their activities to avoid situations that might trigger anxiety.

Renal artery stenosis and renal parenchymal disease can cause increased secretion of renin resulting in severe hypertension. However, a detectable serum renin level does not exclude PHEO,

TABLE 11–16 Differential diagnosis of pheochromocytoma.

Acute intermittent porphyria
Autonomic epilepsy
Cardiac arrhythmias
Clonidine withdrawal
Coronary vasospasm
Encephalitis
Erythromelalgia
Essential hypertension
Hypertensive crisis associated with:
Cerebrovascular accidents
Surgery
Acute pulmonary edema
Severe pain
Hypertensive crisis of MAO inhibitors
Hypoglycemia
Hypogonadal hot flushes
Lead poisoning
Mastocytosis
Migraine and cluster headache
Renovascular hypertension
Sleep apnea
Sympathomimetic drug ingestion
Thyrotoxicosis
Toxemia (eclampsia) of pregnancy

because catecholamines can stimulate renin secretion, and PHEOs can secrete renin ectopically. Furthermore, large PHEOs and PGLs arising near the renal hilum can occlude the renal artery, causing concomitant renovascular hypertension.

Hypogonadism can cause vasomotor instability in both women and men; attacks of flushing, sweating, and palpitations can mimic symptoms seen with PHEO. Factitious symptoms may be caused by surreptitious self-administration of various drugs such as epinephrine. Hyperthyroidism can cause heat intolerance, sweating, palpitations, and systolic hypertension with a widened pulse pressure. Carcinoid syndrome causes flushing during attacks but usually without pallor, hypertension, palpitations, or diaphoresis.

Obstructive sleep apnea can cause systemic hypertension; recurrent nocturnal hypoxia results in repeated episodes of stressful arousal that cause bursts of secretion of catecholamines, particularly epinephrine. Sleep apnea has been reported to cause misleading increases in the urinary excretion of catecholamines.

Patients with erythromelalgia can have episodic hypertension, but it is associated with flushing of the face and legs during the attack; patients with PHEO typically have facial pallor during attacks. With erythromelalgia, patients have painful erythema and swelling in the legs that is relieved by application of ice; such symptoms are not characteristic of PHEO.

Patients who have intermittent bizarre symptoms may have their blood pressure and pulse checked during a symptomatic episode with a home blood pressure meter or an ambulatory blood pressure monitor. Those who are normotensive during an attack are not likely to harbor a PHEO.

PHEOs and PGLs often present with abdominal pain and vomiting. Such symptoms are similar to those of an intra-abdominal emergency, particularly in the presence of leukocytosis and fever,

which can also be seen with PHEOs. Abdominal pain usually prompts a CT scan of the abdomen, which generally shows the PHEO or PGL. Even after detection on CT scan, PHEOs and juxtarenal PGLs may be mistaken for renal carcinoma. Large left-sided PHEOs are often mistaken for carcinoma of the tail of the pancreas.

Neuroblastoma is the most common extra-cranial solid malignancy of childhood. It is also the most common malignancy in infants under 18 months old. Neuroblastomas are derived from the embryonic neural crest of the peripheral sympathetic nervous system. They most often arise in the adrenal gland, but can also develop in sympathetic nerve ganglia near the cervical or thoracic vertebrae or in the pelvis. They metastasize to bones, lymph nodes, liver, and skin. Symptoms depend upon the age of the patient, site of origin, degree of metastatic involvement, and the systemic response to the tumor. Infants usually present with localized disease (Stage 1 or 2) or with a special disseminated pattern of disease (Stage 4S—infants with metastatic disease to liver and/or skin) associated with a favorable outcome. In contrast, most children over 1 year of age present with advanced disease (Stage 3 or 4). Unfavorable biologic features include amplification of myelomatosis viral-related oncogene, neuroblastoma (MYCN), deletion or loss of heterozygosity of chromosome 1p or 11q and gains at 17q. Favorable biologic features include hyperdiploidy and overexpression of the gene encoding the nerve growth factor receptor, tyrosine kinase A (TrkA). About 85% of affected children secrete excessive catecholamines—but rarely in sufficient amounts to cause symptomatic hypertension or the paroxysms typical of PHEOs. Most neuroblastomas concentrate ^{123}I-MIBG but they can be distinguished from PHEOs and PGLs by clinical and histologic criteria.

Localization Studies for Pheochromocytoma

There are several available imaging modalities for PHEO/PGL, each having unique sensitivity and specificity. There is no single imaging study that is 100% sensitive and specific. Generally, when a PHEO or PGL is suspected, the initial diagnosis is best made biochemically. The initial localization scan is with CT or MRI of the abdomen and pelvis, which will detect about 95% of these tumors. However, since PGLs can arise in the chest, further scanning of the chest may be required. Diagnostic confirmation that the tumor is a PHEO or PGL may be done with either ^{123}I-MIBG or ^{18}F-FDA positron emission tomography (PET) scanning; unfortunately, these scans are only 78% sensitive for these tumors. Scanning with ^{18}F-FDG or ^{18}F-FDA PET is more sensitive for detecting metastases than is ^{123}I-MIBG.

A. Computed tomography (Figure 11–11)   After a PHEO has been diagnosed by clinical and biochemical criteria, hypertension must first be controlled (discussed later), because intravenous contrast can precipitate a hypertensive crisis. The PHEO must then be localized. It is useful to perform an initial nonenhanced (without intravenous contrast) CT of the adrenals because the density of an adrenal tumor can be better approximated without
FIGURE 11–11 Left infrarenal PGL shown by CT scanning. The diagram on the right identifies many of the visible structures.

intravenous contrast. An adrenal mass with a density of less than 10 Hounsfield units (HU) is unlikely to be a PHEO. CT scanning of the entire abdomen (from the diaphragm through the pelvis) is obtained with intravenous nonionic contrast-enhanced and delayed contrast-enhanced imaging. Thin-section (2-5 mm) cuts should be obtained through the adrenals with an adrenal protocol that specifically looks for a vascular tumor blush and determines rate of contrast washout. PHEOs tend to have a tumor blush and slower contrast washout than adrenocortical adenomas. Hypertensive crises have been provoked in patients with PHEO/PGL who receive intravenous contrast. Ionic intravenous contrast frequently triggers hypertension, while nonionic intravenous contrast infrequently triggers hypertension. Therefore, all patients with suspected PHEO/PGL should have hypertension controlled before receiving intravenous CT contrast, and nonionic contrast is strongly preferred. Care must be taken in patients with contrast allergy, since glucocorticoids that are typically given by protocol to such patients can precipitate hypertensive crisis in patients with secretory PHEO/PGL. Glucagon should not be used during a CT because it may provoke a hypertensive crisis.

If no mass is discovered, ^{123}I-MIBG imaging may be obtained or the CT scan may be extended into the chest in search of a PGL—or both procedures may be employed. The great majority of PHEOs are over 2 cm in diameter, well within the resolution capacity of the CT scan.

The overall sensitivity of CT scanning for an adrenal PHEO is about 90%—and over 95% for PHEOs that are over 0.5 cm in diameter. However, CT scanning is less sensitive for the detection of small adrenal PHEOs or adrenal medullary hyperplasia; this becomes an important issue in patients with MEN 2 or VHL disease. CT is also less sensitive for detecting extra-adrenal PGLs and early recurrent tumors in the adrenal surgical bed. CT will not detect small metastases or some metastases that strictly involve the bone marrow without osteoclastic activity. Metal surgical clips pose problem for CT scanning, causing distortion artifact and reducing the resolution of the scan.

B. Magnetic resonance imaging   MRI is useful in the diagnosis of adrenal PHEOs, PGLs, and metastatic disease. It may be used with or without gadolinium contrast. However, intravenous gadolinium contrast does not cause hypertensive crisis and improves resolution for metastases, particularly hepatic metastases. MRI scanning with intravenous gadolinium contrast is also useful for patients with a known allergy to intravenous iodinated CT contrast agents. MRI is the scanning technique of choice in children and during pregnancy, because it involves no radiation exposure. Since MRI scanning delivers no radiation, it is preferred for serially scanning patients known to harbor a gene mutation predisposing them to PHEO/PGL.

MRI can help determine whether an adrenal mass is a PHEO when biochemical studies are inconclusive. On MRI T1-weighted images, PHEOs have a dull signal (due to lack of fat cells), similar to kidney and muscle, distinguishing it from adrenal cortical adenomas, which contain fat and therefore have an intensely bright signal on T1-weighted images. The hypervascularity of PHEOs makes them appear bright on MRI T2-weighted images, without signal loss on opposed phase imaging. However, other adrenal malignancies, adrenal adenomas, and hemorrhages can also appear bright on MRI T2-weighted images. Therefore, MRI scanning cannot definitively identify an adrenal mass as a PHEO. MRI of the abdomen has a sensitivity of about 95% for adrenal PHEOs over 0.5 cm in diameter. Like CT scanning, MRI is less sensitive for the detection of extra-adrenal PGLs, metastatic disease, and recurrent small tumors in the adrenal surgical bed. MRI is helpful in visualizing PGLs that are intracardiac, juxtacardiac, or juxtavascular; MRI is particularly important for patients with PGLs adjacent to the vena cava or renal vein to detect vascular invasion. MRI is superior to CT in visualizing PGLs of the bladder wall. MRI can visualize some metastases to bone suspected on ^{123}I-MIBG imaging or PET scanning. Another advantage of MRI scanning is that retained internal metallic surgical clips do not cause the distorting reflection artifacts that occur with CT scanning.

The disadvantages of MRI scanning include expense and its inability to crisply image lungs (due to movement artifact).

Also, morbidly obese patients may not be able to fit into a standard helical MRI scanner; open MRI scanners can be used but are generally less sensitive. Claustrophobic patients require a sedative before the scan or an open MRI. Patients with internal pacemakers or defibrillators may not have MRI scans; nor may patients with implanted neural stimulators, cochlear implants, Swan-Ganz catheters, insulin pumps, cerebral aneurysm clips, ocular metallic foreign bodies, or retained metal shrapnel or bullets. Patients with retained surgical clips, artificial heart valves and joints may have MRI imaging; the spine may be imaged in patients with spinal hardware, but the imaging can be distorted.

C. Metaiodobenzylguanidine scanning (Figure 11–12 and Table 11–17)

MIBG is a guanidine derivative that resembles norepinephrine and is actively transported into adrenal medullary cells via the norepinephrine transporter system, selectively accumulating in neurosecretory granules. Unlike norepinephrine, MIBG has low affinity for catecholamine receptors and is not metabolized.

Scintigraphy using ^{123}I-MIBG or ^{131}I-MIBG is useful for determining whether an adrenal mass is a PHEO, for imaging occult PGLs, and for confirming whether a certain extra-adrenal mass is a PGL or neuroblastoma. MIBG scanning is also useful for screening patients for metastases. MIBG uptake can often be seen in apparently nonfunctioning PHEOs.

The isotope that is preferable for precise imaging is ^{123}I-MIBG, because ^{123}I emits γ radiation at lower energy (159 keV) than does ^{131}I (364 keV). The lower-energy γ emissions allow crisper images

FIGURE 11–12 ^{123}I-metaiodobenzylguanidine (^{123}I-MIBG) scan of a woman with a large left PHEO. Normal ^{123}I-MIBG uptake is seen in the liver, salivary glands, and heart. ^{123}I-MIBG is renally excreted and is visible in the bladder.

TABLE 11–17 Drugs that potentially inhibit MIBG uptake by pheochromocytomas and paragangliomas. Inhibition can persist up to 2 weeks.

Antidepressant inhibitors of norepinephrine reuptake: bupropion, clomipramine, desvenlafaxine, duloxetine, levomilnacipran, mirtazapine, tricyclic drugs, venlafaxine
Antiemetics: metoclopramide, prochlorperazine, promethazine
Antipsychotics: phenothiazines, haloperidol, thiothixene
Amphetamines: amphetamine, dextroamphetamine, lisdexamfetamine, methamphetamine
Anorexic diet medications: benzphetamine, diethylpropion, phendimetrazine, phentermine, sibutramine
Antihypertensive: labetalol (2-6 weeks)
CNS stimulants: cocaine, methylphenidate, dexmethylphenidate
Decongestants (oral, nasal, ophthalmic): pseudoephedrine, ephedrine, phenylpropanolamine, naphazoline, oxymetazoline, propylhexedrine, tetrahydrozoline, xylometazoline
Herbal therapies: ephedra (ma huang), St. John's Wort, yohimbine
Monoamine oxidase inhibitors (MAOi): isocarboxazid, linezolid, phenelzine, selegiline, tranylcypromine

with ^{123}I-MIBG scanning as well as single photon emission computed tomography (SPECT). ^{123}I-MIBG SPECT scanning is more sensitive than ^{123}I-MIBG planar imaging for detecting small metastases and has the advantage of being able to do the scanning on the day following injection of the isotope. SPECT scanning with ^{123}I-MIBG can be combined with CT to produce a three-dimensional fusion scan; the resultant combined images can help distinguish whether a given mass has ^{123}I-MIBG uptake.

^{123}I-MIBG scanning has an overall sensitivity of 82% and a specificity of 82% for PHEOs and PGLs combined. The sensitivity of ^{123}I-MIBG scanning is 88% for primary adrenal PHEOs and 67% for PGLs, with an overall sensitivity of 78% for primary PHEO/PGL tumors. The sensitivity of ^{123}I-MIBG scanning for metastases is lower at only 57%. Scanning with ^{123}I-MIBG is more sensitive for PHEOs that are benign, unilateral, adrenal, capsule-invasive, and sporadic. Scanning with ^{123}I-MIBG is less sensitive for bilateral, malignant, extra-adrenal, noninvasive, and MEN 2-related or VHL-related PHEOs.

To block the thyroid's uptake of free radioiodine, saturated solution of potassium iodide, five drops orally three times daily, is given before the injection and daily for 4 days after ^{123}I-MIBG and for 7 days after ^{131}I-MIBG. Scanning is performed 24 to 48 hours after ^{123}I-MIBG infusion and 48 to 72 hours after ^{131}I-MIBG infusion.

False-negative MIBG scans are seen in about 15% of cases of either benign or malignant PHEO. False-negative scans can occur in patients who have taken certain drugs (eg, tricyclic antidepressants or cyclobenzaprine) within 6 weeks. Other drugs that can cause false-negative scans when taken within 2 weeks include amphetamines, phenylpropanolamine, haloperidol, phenothiazines, nasal decongestants, cocaine, and diet pills. Labetalol reduces MIBG uptake, but the scan can still be done, albeit with suboptimal sensitivity (Table 11–17). When plasma norepinephrine levels are over 500 pg/mL (3 nmol/L), cardiac visualization is reduced on ^{18}F-dopamine PET scanning. This phenomenon is believed due to competitive inhibition of uptake-1 by high levels

of circulating norepinephrine. Therefore, it is likely that very high endogenous norepinephrine levels may reduce the sensitivity of ^{123}I-MIBG scanning as well as PET scanning that employs ^{18}F-DA or ^{19}F-DOPA because these compounds are transported into PHEOs, PGLs, and their metastases by the same uptake mechanism.

False-positive MIBG scans occur infrequently. Following ^{123}I-MIBG, some uptake in a normal adrenal medulla is seen in 32% to 75% of patients at 24 hours. Following ^{131}I-MIBG, uptake in a normal adrenal medulla is seen in 16% of normals at 48 hours. Adrenal uptake is often asymmetric and can be misinterpreted as showing a tumor. MIBG has renal excretion, so the renal pelvis and bladder are usually visualized on scanning and must be distinguished from tumor. If a patient is being evaluated for a bladder mass (to exclude a PGL), a bladder catheter may be inserted and the bladder flushed with saline to distinguish tumor from renal excretion of isotope. Urine contamination with ^{123}I-MIBG can also cause a false-positive scan. False-positive results have been reported with adrenal carcinomas and infections such as actinomycosis. The salivary glands are typically visualized since they are richly innervated. The heart, liver, and spleen normally take up some ^{123}I-MIBG. Some isotope is excreted in the stool, and intracolonic collections can be mistaken for tumor. When there is doubt about whether an area of uptake is a tumor, scanning can be repeated the next day, preceded by a laxative if required.

D. Positron emission tomography (Figure 11–13)   PET scanning can be performed shortly after the intravenous infusion of short-lived isotopes that are tagged to a compound that is preferentially absorbed by tumor tissue.

PET scanning has certain advantages over MIBG scanning. PET scanning can be done almost immediately. This gives it some advantage over MIBG scanning, which must be delayed for 24 to 48 hours after the injection to allow dissipation of background radiation. PET scanning does not require pretreatment with iodine to protect the thyroid, as is necessary with MIBG scanning. However, PET scanning is very expensive. The isotope ^{18}F has a half-life of just 2 hours and must be produced in a cyclotron, so ^{18}F-FDG or ^{18}F-FDA PET scanning is practical only at medical centers that have a cyclotron nearby.

1. **PET scanning with ^{18}F-FDG** Deoxyglucose (DG) is absorbed by tissues with active metabolism, including tumors. For PET scanning, DG is tagged with ^{18}F to produce fluorodeoxyglucose, or ^{18}F-FDG. This scan is widely available as a fusion scan with CT, ^{18}F-FDG PET/CT. This scan's sensitivity is 88% for nonmetastatic PHEO/PGL and 76% for metastatic PHEO/PGL. The sensitivity of ^{18}F-FDG-PET/CT is lower for indolent tumors and for patients who are diabetic or who are not fasting before the scan. ^{18}F-FDG-PET localizes in other tissues with a high metabolic rate, including areas of inflammation, brown fat, shivering muscles, but such areas of PET uptake can be distinguished from tumors by the lack of a CT correlate. However, ^{18}F-FDG-PET/CT detects other tumors besides PHEO/PGL and is, therefore, less specific for PHEO/PGL than is ^{18}F-FDA-PET or ^{123}I-MIBG scanning. ^{18}F-FDG/CT scanning is usually performed without CT contrast, such that

FIGURE 11–13 ^{18}F-deoxyglucose (^{18}FDG) PET/CT fusion scan. Patient had a retroperitoneal PGL that was resected. ^{18}FDG-PET/CT fusion scan shows a large metastasis involving the left acetabulum and inferior pubic ramus. The metastasis had negligible ^{123}I-MIBG uptake. A metastasis causing L4 compression had been treated previously with radiation therapy.

it misses certain tumors, particularly indolent PGL/PHEO metastases to liver, where the hepatic metastases may be invisible on both ^{18}F-FDG scanning as well as noncontrast CT scanning.

2. **PET scanning with ^{18}F-FDA** PET scanning may also be performed using radioisotope-tagged dopamine: 6-[^{18}F] fluorodopamine (^{18}F-FDA-PET). This scan is more specific for PGL and metastatic PHEO than is ^{18}F-FDG-PET/CT, because dopamine is a substrate for the norepinephrine transporter in tumor tissue. The sensitivity of ^{18}F-FDA-PET is 78% for nonmetastatic PHEO/PGL and 76% for metastatic PHEO/PGL. It is not widely available, but is generally more sensitive than ^{123}I-MIBG scanning, particularly in patients who harbor VHL or MEN 2 germline mutations. It is particularly useful for detecting other neuroendocrine tumors and PHEO/PGL metastases that are not visualized by scanning with ^{123}I-MIBG or ^{18}F-FDG and for tumors and metastases in patients with VHL disease.

E. Somatostatin receptor (SSTR) imaging SSTRs   are cell-surface G protein–coupled receptors, and there are five subtypes. About 70% of PHEOs express SSTRs, particularly types 2 and 4. SSTR imaging detects some metastases not visible on MIBG scanning, and vice versa. SSTR imaging has been reported to detect a cardiac PGL that was not visible on MIBG scanning.

111In-octreotide: Octreotide is a stable 8 amino acid analog of somatostatin with a high affinity for type 2 receptors. For imaging, octreotide is coupled with 111In-diaminetriaminepentacetate (DTPA). 111In has a half-life of 2.8 days and γ emissions of 173 keV and 247 keV. Scanning with 111In-labeled octreotide, known as SSTR imaging (SRI), has a sensitivity of only 25% for adrenal PHEOs and juxtarenal PGLs. This low sensitivity is due to high uptake of 111In-octreotide by the kidneys as well as renal excretion. However, 111**In-octreotide** detects 87% of PHEO metastases and is also a sensitive technique for detecting PGLs of the head and neck (chemodectomas). 111In-octreotide has physiologic uptake in the kidneys, thyroid, pituitary, salivary glands, gallbladder, bowels, spleen, liver, and mammary glands. Infection and recent surgery sites can also have misleading uptake of 111In-octreotide.

68Ga-DOTATATE-PET: This scans employs a somatostatin congener with increased affinity for SSTRs. It is tagged with 68Ga, a positron emitter, to allow PET scanning; when fused with a simultaneous CT scan; this provides exceptional sensitivity and clarity in the fusion scan. This scan is proving to be superior to all imaging modalities, particular for detecting PHEO/PGL metastases in patients with SDHB germline mutations.

F. Ultrasound imaging   On transabdominal ultrasound, an adrenal PHEO typically appears as a well-defined mass. Large PHEOs tend to develop internal hemorrhagic necrotic cysts, making the tumor appear heterogenous. Transabdominal ultrasound is most sensitive in slender individuals, in whom 85% of adrenal PHEOs can be visualized. However, ultrasound lacks specificity, such that a PHEO is not distinguishable from an adrenal adenoma or a mass in the superior pole of a kidney. Likewise, a left adrenal PHEO may be mistaken for a pancreatic tail tumor, and a right adrenal PHEO may be mistaken for a hepatic mass. Ultrasound may be used for initial imaging for PHEO in pregnant women, infants, and young children, although MRI is superior. Ultrasound is also useful for imaging and surveillance of neck PGLs. Ultrasound examinations have also been performed endoscopically, from the stomach and duodenum, with a longitudinal sector array, yielding sensitive detection of small adrenal PHEOs, lymphangitic metastases, and local recurrences. For pelvic and bladder PGLs, pelvic transvaginal ultrasound is very helpful for tumor localization and surveillance.

INCIDENTALLY DISCOVERED ADRENAL MASSES

Clinically unapparent adrenal nodules are discovered incidentally on about 4% of all abdominal CT or MRI scans that are performed for unrelated reasons (see Computed Tomography, discussed earlier.) Such nodules are known as **adrenal incidentalomas**. The incidence of adrenal nodules increases with age, being about 3% in middle-age and rising to about 10% in the sixth and seventh decades of life. Most such nodules are small, benign adrenal adenomas, with densities below 10 HU on noncontrast CT. However, PHEOs can produce nonspecific symptoms of abdominal pain, nausea, and weight loss, for which CT scans may be performed.

PHEOs account for about 4% of incidentally discovered adrenal masses. In the United States nearly half of the PHEOs diagnosed during life are detected incidentally on an abdominal or chest CT scan performed for other reasons. Therefore, most patients with adrenal nodules, even normotensives, should be screened for PHEO with plasma-fractionated free metanephrines. However, such testing is not mandatory for normotensives whose adrenal nodule has all of the following characteristics: (1) density on unenhanced CT less than or equal to 10 Hounsfeld Units (HU); (2) size less than or equal to 3 cm; (3) morphology not suspicious. A problem arises with metanephrines that are marginally elevated. Such patients with metanephrines that are one to two times higher than the reference range's ULN have about a 30% chance of harboring a PHEO. Those with metanephrines more than twice the ULN have a very high risk of having a PHEO. For apparently nonfunctioning adrenal nodules, it is generally reasonable to observe those that are under 3 cm in maximum diameter. Nonfunctioning nodules that are 3 to 5 cm in maximum diameter require especially close surveillance. Adrenal nodules that are over 5 cm in diameter are generally resected, except for obvious myelolipomas. When a PHEO has been ruled out, patients with an adrenal nodule may be screened for hyperaldosteronism and Cushing syndrome. Of note, hypertensive crisis has been described in patients with PHEO/PGL undergoing the high-dose dexamethasone suppression (DST) test, but not the low-dose DST.

Adrenal Percutaneous Fine-Needle Aspiration (FNA) Cytology

Most PHEO/PGLs can be readily diagnosed on the basis of their clinical, biochemical, and radiologic presentation. FNA cytology is not usually required for the diagnosis of a PHEO/PGL. However, some PHEO/PGLs are discovered incidentally on abdominal CT or ultrasound and may be clinically or biochemically silent. Although there may be a temptation to biopsy such masses, patients with a suspicious adrenal or retroperitoneal mass require testing for PHEO/PGL before any biopsy. There is a 70% risk of complications after percutaneous FNA of PHEO/PGLs. Such complications include: increased difficulty in the tumor's resection (41%), severe hypertension (15%), hematoma (30%), severe pain (25%), and incorrect or inadequate biopsy (25%). FNA cytology can be misinterpreted as a different primary malignancy or a metastasis from another malignancy; this potential for confusion is due to the fact that PHEO/PGLs are rare tumors and have pleomorphic and hyperchromic nuclei. Large left-sided PHEOs have been misdiagnosed as carcinoma of the tail of the pancreas based on CT scanning and FNA cytology. Percutaneous FNA can also disrupt the PHEO capsule and cause seeding of the tumor within the peritoneum.

Medical Management of Patients with Pheochromocytoma and Paraganglioma

Patients need to be treated with oral antihypertensives and stabilized hemodynamically prior to surgery. Patients receiving increasing doses of antihypertensive medications should have daily

measurements of blood pressure and pulse rate in the lying, sitting, and standing positions. Additionally, patients are taught to determine their own blood pressure and pulse rate regularly and during any paroxysmal symptoms. Most clinicians gradually increase antihypertensive medications over 2 or more weeks. However, prolonged preoperative preparation has not proven more effective for preventing intraoperative hypertension than shorter preparation periods. Some hypertensive patients have been admitted emergently for hypertension control and hydration, stabilized, and operated on successfully with intravenous infusion of a vasodilator drug (eg, nicardipine, nitroprusside, nitroglycerin; discussed later). Ideally, the blood pressure should be reduced to an average of 130/85 mm Hg (sitting) or less prior to surgery, while avoiding symptomatic orthostasis. Normotensive patients with PHEO/PGL who have documented increased plasma catecholamine levels are usually prepared for surgery with careful titration of α-blockade and/or calcium channel blockade. However, some normotensive patients, particularly those with PGLs, have truly nonsecreting tumors with completely normal plasma levels of catecholamines and metanephrines; such patients may not require any preoperative antihypertensive preparation, unless they have a clinical history of intermittent hypertension. Similarly, normotensive patients with PGLs secreting only dopamine do not require preoperative antihypertensive medication.

The type of preoperative medical preparation varies by region. In the USA, α-blockade is predominantly used. In Europe, about half the patients receive either nonselective α-adrenergic blockade (phenoxybenzamine) or selective α_1-adrenergic blockade (prazosin); about half receive calcium channel blockade (CCB), usually with nicardipine. Perioperative morbidity is the same with either type of medical preparation. The choice between preoperative α-blockade versus CCB (or a combination of both) is usually determined by local protocols and consultation between the endocrinologist, surgeon, and anesthesiologist and by the individual patient's reaction to the medication.

A. Alpha-adrenergic blockers   Alpha-adrenergic blockers have historically been used for most patients with PHEO in preparation for surgical resection. **Phenoxybenzamine** (10-mg capsules) is an oral nonselective α-blocker that is the most commonly used α-blocking agent. It has a long half-life of about 24 hours. Patients with mild hypertension may be given phenoxybenzamine at a starting dosage of 10 mg once daily, while those with more severe hypertension may receive a starting dosage of 10 mg twice daily. The dose of phenoxybenzamine may be increased by 10 mg every 2 days until the blood pressure falls to an average of 130/85 mm Hg sitting or until symptomatic orthostatic hypotension occurs. Patients who have been normotensive between paroxysms are particularly prone to develop hypotension with phenoxybenzamine. Phenoxybenzamine does not block the synthesis of catecholamines; in fact, the synthesis of catecholamines and metanephrines tends to increase during α-blockade. Therapy with phenoxybenzamine increases the heart rate but decreases the frequency of ventricular arrhythmias. Patients are encouraged to hydrate themselves well. Patients must be monitored daily for symptomatic orthostatic hypotension. Certain adverse effects are

common, including dry mouth, headache, diplopia, inhibition of ejaculation, and nasal congestion. Nasal decongestants should not be used if urinary catecholamine determinations or ^{123}I-MIBG scanning is planned, but antihistamines are acceptable. Phenoxybenzamine is not usually well tolerated as chronic therapy for hypertension in patients with unresectable or metastatic PHEO, and such patients are better treated with calcium channel blockers (discussed later), sometimes together with low-dose α-blockade.

Phenoxybenzamine crosses the placenta and accumulates to levels that are 60% higher in the fetus than in the maternal circulation; this can cause hypotension and respiratory depression in the newborn for several days following birth. Most patients require 30 to 60 mg/d, but the dosage is sometimes escalated to as high as 200 mg/d. However, phenoxybenzamine has a long half-life and excessive α-blockade with phenoxybenzamine can cause prolonged postoperative hypotension. Furthermore, excessive α-blockade may deny a critical surgical indicator (ie, a drop in blood pressure after complete resection of the tumor and aggravation of hypertension during palpation of the abdomen in case of multiple tumors or metastases).

Selective α_1-adrenergic blockers cause relatively less reflex tachycardia and orthostasis, compared to phenoxybenzamine. They also tend to cause less ejaculatory disturbance in men, which is a consideration with long-term use. **Doxazosin** is selective α_1-adrenergic blocker with a half-life of about 22 hours. It is effective in the medical management of PHEO/PGL when given orally in doses of 2 to 16 mg daily. In one series, there was no difference in hemodynamic instability during surgery in patients pretreated with doxazosin versus phenoxybenzamine. **Terazosin** is a selective α_1-adrenergic blocker with a half-life of about 12 hours. Although its usual indication is for benign prostatic hypertrophy, it has been used as an antihypertensive for patients with PHEO/PGL; the starting dose is 1 mg daily with subsequent doses being given twice daily and titrated upward every 2 days to a dose where hypertension is controlled or to a maximum of 10 mg every 12 hours. **Prazosin** is a short-acting selective α_1-adrenergic blocker. Due to its shorter half-life of only 3 hours, prazosin must be given every 8 to 12 hours. The starting dose of prazosin is 0.5 mg every 12 hours, increasing up to 10 mg twice or three times daily, if necessary. Patients treated with prazosin have experienced less postoperative hypotension, due to the drug's short half-life. Prazosin is particularly useful as a perioperative medication for pregnant women with PHEO/PGL who undergo a cesarean section (discussed later). **Urapidil** is an intravenous α_1-adrenergic blocker that has been used for in-hospital control of hypertension prior to surgical resection of PHEOs/PGLs. Urapidil has been successfully administered at constant intravenous infusion rates of 5 mg/h for the first day, increasing (if necessary) to 10 mg/h on the second day, and to 15 mg/h on the third day. In one study, urapidil therapy achieved preoperative hypertension control more rapidly (compared to phenozybenzamine), without any change in clinical outcomes.

Labetalol and carvedilol are combined selective α_1-adrenergic blocker *and* nonselective β-adrenergic blocking drugs with half-lives of about 6.5 and 8 hours, respectively. They should not be

used as the initial medication for treating hypertension in patients with PHEO/PGL, due to their unpredictable initial effects, sometimes causing an initial *increase* in blood pressure due to their nonselective β-blockade. Labetalol also can cause misleading elevations in catecholamine determinations in some assays, and inhibits MIBG uptake into PHEO/PGLs. However, labetalol has proven useful for some patients with metastatic or unresectable PHEO/PGL, especially after other medical therapy has failed. Labetalol is initiated at doses of 100 mg orally every 12 hours, titrating the dose upward every 2 days until the patient is normotensive or to a maximum of 1200 mg every 12 hours.

B. Calcium-channel blockers (CCBs)

Dihydropyridine CCBs are usually excellent antihypertensive agents for patients with PHEO/PGLs. However, they tend to reduce cardiac output and are not preferred for patients with congestive heart failure. Otherwise, CCBs are particularly useful for patients in whom α-blockers have caused adverse reactions, such as orthostatic hypotension or excessive fatigue. CCBs may be added to α-blockers to prepare patients for surgery. Patients who are normotensive between paroxysms are less likely to become hypotensive with CCBs compared to α-blockers. Patients with angina from coronary vasospasm are also best treated with CCBs. Perioperative fluid requirements have been lower among patients who were pretreated with CCBs instead of α-blockers. In a French series, 70 patients with PHEO were successfully prepared for surgery using oral CCBs (usually nicardipine). Nicardipine may be given in doses of 20 to 40 mg orally every 8 hours; nicardipine is also available as a sustained-release preparation that may be given in doses of 30 to 60 mg orally every 12 hours. Patients tend to tolerate CCBs better than α-blockers, such that CCBs are usually preferred for patients with PHEO/PGL who require long-term therapy due to recurrent or metastatic disease. However, some patients prefer α-blockade.

Nifedipine is a calcium channel blocker that is administered as an extended-release (ER) preparation in doses of 30 to 90 mg orally once or twice daily. The half-life of the ER preparation is 7 hours, so twice-daily dosing is preferred. For hypertensive paroxysms (systolic BP persistently above 170 mm Hg), nifedipine 10 mg (chewed pierced capsule) is usually a fast and effective treatment. Chewed nifedipine is generally safe for use by patients with PHEO, who may self-administer the drug at home during paroxysms but only with close blood pressure monitoring. In one small study, nifedipine therapy appeared to improve the uptake of MIBG into PHEOs in 4 of 8 patients at scanning doses. Nifedipine might possibly reduce the growth of PHEO/PGL and metastases, because *in vitro* nifedipine added to cultured PHEO cells reduces their mitotic index and proliferation. However, the effect of nifedipine on PHEO/PGL tumor growth has not been studied in patients.

Amlodipine may also be used for patients with PHEO/PGL in doses of 10 to 20 mg daily, but has a long half-life of 30 to 50 hours. There is little experience with other non-dihydropyridine CCBs (nimodipine, nisoldipine, isradipine, felodipine) for treating patients with PHEO/PGL.

Intravenous dihydropyridine CCBs are useful for hypertensive crisis, particularly during surgery. Nicardipine and clevidipine are both available as intravenous preparations (see Surgical Management of Pheochromocytoma and Paraganglioma, discussed later.)

Non-dihydropyridine CCBs are reported to be less effective for patients with PHEO. Verapamil has been used in a sustained-release preparation, but has been reported to be associated with postoperative pulmonary edema after PHEO resection. Diltiazem provides inadequate intraoperative blood pressure control.

C. Beta-adrenergic blockers

These agents are generally not prescribed for patients with PHEO/PGL tumors until treatment has been started with antihypertensive medications such as α-adrenergic blockers or CCBs. Beta-adrenergic blockade should then be used for treatment of β-adrenergic symptoms such as flushing, pounding heart, or tachycardia. It is important to institute α-blockade first, because blocking vasodilating $β_2$ receptors without also blocking vasoconstricting $α_1$ receptors can lead to hypertensive crisis if serum norepinephrine levels are high.

Nonselective β-blockers block both $β_1$- and $β_2$-adrenergic receptors. The inhibition of vasodilating arterial $β_2$ receptors causes unopposed vasoconstrictive α-adrenergic stimulation that aggravates hypertension. Therefore, nonselective β-blockers should ordinarily not be administered to patients with PHEO/PGL. Nonselective β-blockers include: nadolol, pindolol, propranolol, and timolol. Labetalol and carvedilol are different nonselective β-blockers that additionally block $α_1$ receptors.

Selective β-blockers specifically block $β_1$-adrenergic receptors at low doses. This leads to a rather selective reduction in heart rate without unopposed α-receptor dependent hypertension. However, at higher doses, these β-blockers also block $β_2$-adrenergic receptors and can cause a paradoxical worsening of hypertension. Selective β-blockers include: metoprolol succinate ER, atenolol, betaxolol, bisoprolol, nebivolol, and esmolol. Nebivolol has vasodilating activity through enhancement of nitric oxide release. Esmolol is the preferred intravenous preparation.

D. Angiotensin-converting enzyme inhibitors

ACE inhibitors have successfully treated hypertension in patients with PHEO/PGL, but not as the sole agent. Angiotensin receptor blockers have also been successfully added to multidrug antihypertensive therapy. Catecholamines stimulate renin production. In turn, renin stimulates the production of angiotensin I, which is converted by ACE to angiotensin II; this can be blocked by ACE inhibitors. Furthermore, PHEOs have been demonstrated to have angiotensin II-binding sites. ACE inhibitors are contraindicated in pregnancy (discussed later).

E. Metyrosine (α-methyl-para-tyrosine)

Metyrosine inhibits the enzyme tyrosine hydroxylase, which catalyzes the first reaction in catecholamine biosynthesis. Because of its potential side effects, it is usually used only to treat hypertension in patients with metastatic PHEO. Metyrosine is administered orally as 250-mg capsules, beginning with one every 6 hours; the dose is titrated

upward every 3 to 4 days according to blood pressure response and side effects. Most patients can tolerate 2 g/d, but higher doses usually cause side effects. The maximum dosage is 4 g/d. Catecholamine excretion is usually reduced by 35% to 80%. Preoperative treatment with metyrosine tends to reduce intraoperative hypertension and arrhythmias; however, postoperative hypotension is likely to be more severe for several days. Side effects of metyrosine include sedation, psychiatric disturbance, extrapyramidal symptoms, and potentiation of sedatives and phenothiazines. Crystalluria and urolithiasis can occur, so adequate hydration is mandatory. Metyrosine does not inhibit MIBG uptake by the tumor, allowing concurrent ^{123}I-MIBG scanning or treatment with high-dose ^{131}I-MIBG.

F. Octreotide   Octreotide has not been formally studied or approved for use in patients with PHEO/PGL. However, octreotide (100 μg subcutaneously three times daily) has been reported to reduce hypertensive episodes and catecholamine excretion in a man with PHEO whose hypertensive paroxysms were uncontrolled using other means. Octreotide therapy has been observed to reduce bone pain in a woman with a malignant PGL whose skeletal metastases were avid for ^{111}In-labeled octreotide. Octreotide therapy is usually begun at a dose of 50 to 100 μg injected subcutaneously every 8 hours. Side effects are common and may include nausea, vomiting, abdominal pain, and dizziness. If the drug is tolerated, the dose can be titrated upward to a maximum of 1500 μg daily. Octreotide LAR can be given as subcutaneous injections in doses of 10 to 40 mg every 4 weeks.

G. Activities to avoid   Vigorous exercise, particularly involving bending or heavy lifting, can aggravate hypertension in some individuals with PHEO/PGL, so mild exertion or rest is best during preparation for surgery. Emotional stress can provoke hypertensive attacks, so arguments and stressful situations are best avoided.

H. Foods to avoid   Intravenous tyramine causes hypertension in most patients with PHEO/PGL. While dietary tyramine has not been studied in patients with secretory PHEO/PGL, it is known that dietary tyramine can provoke hypertensive crisis in patients taking MAO inhibitor antidepressants. Therefore, although strict dietary precautions are not required, it is reasonable for patients with a known secretory PHEO/PGL to avoid consuming large amounts of foods with high tyramine content during preparation for surgery such as red wine, tap beers, aged dairy products, aged meats, fermented or pickled fish, liver, protein extracts, overripe fruit, soybeans, tofu, fava bean pods, bean pastes, brewer's yeast pills, marmite, and vegemite.

Surgical Management of Pheochromocytoma and Paraganglioma

A. Perioperative preparation   Prior to surgery, patients should be reasonably normotensive on medication, with an average blood pressure of 130/85 mm Hg or less, without symptomatic orthostasis (discussed earlier). They should also be well hydrated. It is ideal for patients to be admitted for administration of intravenous fluids at least 1 day prior to surgery; however, this is rarely done due to cost considerations. Patients may predonate blood for autologous transfusion. The transfusion of two units of blood within 12 hours before surgery reduces the risk of postoperative hypotension. Blood pressure must be monitored continuously during surgery. This requires placement of an arterial line, preferably in a large artery that is not prone to spasm (eg, femoral artery). A central venous pressure line helps determine the volume of fluid replacement. For certain high-risk patients with congestive heart failure or coronary artery disease, a pulmonary artery (Swan-Ganz) line may be inserted preoperatively to further optimize fluid replacement. Constant electrocardiographic monitoring is mandatory. Severe hypertension can occur—even in fully blocked patients—during bladder catheterization, intubation, or surgical incision. During laparoscopic surgery, catecholamine release is typically stimulated by pneumoperitoneum and by tumor manipulation. However, laparoscopic procedures cause less fluctuation of catecholamine levels and blood pressure than do open surgeries. All antihypertensive medications (discussed later) that might be required should be available and should be in the operating room well in advance.

Arterial embolization of the tumor can be performed immediately prior to surgery. This may be beneficial to the surgeon, particularly for the open resection of very large PGLs that tend to be extremely vascular and difficult to resect, due to blood loss and venous oozing. Embolization of neck PGLs is an established intervention. Secretory PGLs can also be embolized preoperatively. An experienced interventional radiologist must perform such embolizations with full monitoring and an anesthesia team in attendance.

The major problem during surgery for PHEO/PGL is hemodynamic instability. Serious blood pressure variations are more common in patients whose blood pressure has not been adequately controlled preoperatively. Intraoperative hemodynamic instability is also more common in patients with higher plasma norepinephrine levels and larger tumor size.

B. Antihypertensive and antiarrhythmic drugs

1. **Calcium channel blockers** These are effective therapies for intraoperative hypertension. They can cause reflex tachycardia that can be controlled with intravenous β-blockers (eg, esmolol). Nicardipine is administered as an intravenous infusion, starting at a dose of 5 mg/h and increasing by 2.5 mg/h every 5 to 15 minutes up to 15 mg/h. Nicardipine was successfully used as the sole intraoperative vasodilating agent in one French series of 70 patients and in another series of 19 patients. Its half-life is 9 hours. Clevidipine has a shorter half-life of 1 to 15 minutes. It is available for intravenous infusion at a dose of 1 to 2 mg/h, doubling the dose after 90 seconds, then increasing in smaller increments at longer intervals (5-10 minutes) up to 4 to 6 mg/h or a maximum of 16 mg/h.

2. **Phentolamine** It is a parenteral α-adrenergic blocker that has a short half-life of 19 minutes. It can be given intravenously in bolus doses, starting with a trial dose of 2.5 mg, followed by 5 mg (children, 1-3 mg) and repeating in doses of 5 to 15 mg as

needed for blood pressure control. Phentolamine may also be given by intravenous infusion at a rate of 0.5 to 1 mg/min. Side effects include hypotension, tachycardia, cardiac arrhythmias, nasal stuffiness, nausea, and vomiting.

3. **Nitroprusside** It is given by intravenous infusion and is an effective drug for managing hypertensive episodes; advantages include widespread familiarity with its use and its short half-life of 2 minutes. Nitroprusside is initiated at 0.25 to 0.3 µg/kg/min and titrated for the desired effect. The maximum infusion rate is 10 µg/kg/min for 10 minutes. High infusion rates should not be given for prolonged periods; long-duration (over 6 hours) nitroprusside infusion rates above 2 µg/kg/min cause cyanide accumulation and toxicity. Cyanide toxicity causes metabolic acidosis and an increase in venous oxygen saturation (>90%) in severe cases. If cyanide toxicity is suspected, the nitroprusside infusion must be stopped or slowed. In the United States, there are two different cyanide antidote kits available. (1) The conventional kit contains amyl nitrite, sodium nitrite, and thiosulfate. Administer an amyl nitrite crushed ampule at the end of the endotracheal tube or under the patient's nose and give 10 mL 3% sodium nitrite intravenously. Also administer 25% sodium thiosulfate solution (50 mL) intravenously. (2) Additionally, hydroxocobalamin (Cyanokit) is available for intravenous administration at a dose of 5 g (children, 70 mg/kg). Coadministration of sodium thiosulfate (1 g/100 mg nitroprusside) prevents cyanide accumulation. Nitroprusside must be administered cautiously, since it can cause precipitous and profound hypotension, resulting in irreversible ischemic injuries.

4. **Nitroglycerin** It is given by intravenous infusion and is effective therapy for perioperative hypertension. Nitroglycerin infusions are initiated at 5 µg/min and increased by 5 µg/min every 3 to 5 minutes until target blood pressure is achieved or a dose of 20 µg/min is reached; if the response has been insufficient, the dose can be increased by 10 to 20 µg/min every 5 minutes to a maximum of 100 µg/min. Because nitroglycerin adheres to polyvinyl chloride tubing, non-PVC infusion sets must be used. Nitroglycerin infusions can cause headache and hypotension. Methemoglobinemia has occurred during prolonged high-dose infusions and is manifested by cyanosis in the presence of a normal arterial pO_2. The therapy for methemoglobinemia consists of immediately stopping the nitroglycerin and giving methylene blue, 1 to 2 mg/kg intravenously.

5. **Beta-blockers** Atrial tachyarrhythmias may be treated with intravenous atenolol in 1-mg boluses or by constant intravenous infusion of esmolol, a short-acting β-blocker. Esmolol is given as an initial dose of 500 µg/kg intravenously over 1 minute, then continued at 50 µg/kg/min. If required, the infusion rate may be increased by 50 µg/kg/min every 4 minutes.

6. **Magnesium sulfate** It is useful for suppressing ventricular arrhythmias and also for managing hypertension during resection of a PHEO/PGL, particularly during pregnancy. Magnesium sulfate may be given as a 4-g intravenous bolus, followed by 3 to 20 mg/min IV infusion.

7. **Lidocaine** It may be used to treat cardiac ventricular arrhythmias. In adults, lidocaine is administered with a loading dose of 150 to 200 mg over about 15 minutes, or as a series of smaller boluses. This is followed by a maintenance infusion of 2 to 4 mg/min in order to achieve a therapeutic plasma level of 2 to 6 µg/mL.

8. **Drugs to avoid** *Atropine* should not be used as preoperative medication for patients with PHEOs because it can precipitate arrhythmias and severe hypertension. Metoclopramide, glucagon, and glucocorticoids can also precipitate a hypertensive crisis. *MAO inhibitor antidepressants* can provoke hypertensive crisis by blocking the metabolism of catecholamines. Other medications that can elicit hypertensive crisis include decongestants (eg, pseudoephedrine), epinephrine, amphetamines and amphetamine derivatives, and cocaine. *Labetalol* is not recommended for preoperative or intraoperative management of PHEOs because it may aggravate post-resection hypotension. It can also paradoxically aggravate hypertension early in the course of treatment, because its β-blocking effect may occur initially, allowing a brief period of unopposed α-receptor stimulation. Labetalol also inhibits MIBG uptake and causes misleading elevations in catecholamine determinations in certain assays. *Diazoxide* has been ineffective against hypertension caused by PHEO/PGL.

C. Anesthesia Anesthetic agents such as intravenous propofol, enflurane, isoflurane, sufentanil, alfentanil, and nitrous oxide appear to be safe and effective. Atropine should not be used. Muscle relaxants with the least hypertensive effect should be employed (eg, vecuronium). Intraoperative hypertension can be managed by increasing the depth of anesthesia and by intravenous vasodilators for blood pressures over 160/90 mm Hg. Serum catecholamine levels drop sharply after adrenal vein ligation and profound hypotension can occur suddenly after resection of a PHEO. Therefore, it is prudent to stop the vasodilator infusion just prior to adrenal vein ligation.

D. Operative management Perioperative mortality is about 2.4% overall, but morbidity rates of up to 24% have been reported. Surgical complications do occur and include splenectomy, which is more common with open abdominal exploration than with laparoscopic surgery. Reported surgical complication rates have been higher in patients with severe hypertension and in patients having reoperations. Surgical morbidity and mortality risks can be minimized by adequate preoperative preparation, accurate tumor localization, and meticulous intraoperative care.

1. **Laparoscopy** Most PHEOs can be resected laparoscopically, which has become the procedure of choice for removing most adrenal neoplasms that are under 6 cm in diameter. Adrenal laparoscopic surgery is usually performed through four subcostal ports of 10 to 12 mm. Laparoscopic surgery is widely used now that preoperative localization of the tumor is possible. However, tumors that are invasive or over 6 cm in diameter are more difficult to resect laparoscopically and may require open surgery. For larger PHEOs/PGLs, a lateral laparoscopic approach can be used, because it affords greater opportunity to explore the abdomen and inspect the liver for metastases. For patients with a small adrenal PHEO and for those who have had prior abdominal surgery, a posterior laparoscopic approach may be preferred.

The laparoscope allows unsurpassed magnified views of the PHEO and its vasculature. PHEOs are bagged to reduce the risk of fragmentation and spread of tumor cells within the peritoneum or at the port site. Larger tumors can be removed through laparoscopic incisions that can be widened for the surgeon's hand (laparoscopic-assisted adrenalectomy). With laparoscopic surgery, hypotensive episodes are less frequent and

less severe. Laparoscopic adrenalectomy has other advantages compared with open adrenalectomy: less postoperative pain, faster return to oral foods, and shorter hospital stays (median 3 days vs 7 days for the open approach). This approach is the least invasive for the patient, who can usually begin eating and ambulating the next day. The laparoscopic approach may be used during pregnancy. The technique has also been used successfully for certain extra-adrenal PGLs. Surgical-related mortality has been reduced to 3% at referral centers.

2. **Needlescopic adrenalectomy** This procedure uses three sub-costal ports of 3 mm, with a larger umbilical port for tumor removal. In one series of 15 patients, this technique reduced surgical times and recovery time compared with the standard laparoscopic approach. However, more extensive experience with this technique is required.

3. **Adrenal cortex-sparing surgery** All patients undergoing bilateral total adrenalectomies require life-long glucocorticoid and mineralocorticoid hormone replacement. To avoid adrenal insufficiency, patients with bilateral PHEOs and those with unilateral PHEOs but with highly penetrant familial PHEO/PGL syndromes (especially MEN 2 and VHL) who are at high risk for developing a contralateral PHEO, have had successful laparoscopic partial adrenalectomy during resection of small adrenal PHEOs, sparing some of the adrenal cortex. Such adrenal-sparing surgery is difficult and risks a local recurrence of the PHEO, especially in patients with MEN2.

4. **Open laparotomy** Open laparotomy is indicated for patients with particularly large PHEOs or PGLs, or for those with intra-abdominal metastases that require debulking. Large vascular PGLs can be considered for preoperative arterial embolization, but its efficacy is uncertain. An open anterior midline or subcostal approach usually yields adequate exposure. For patients with PGLs of the urinary bladder, a partial cystectomy can sometimes be curative. Other patients with larger bladder PGLs require a total cystectomy and construction of a diverting ureteroenterostomy if the tumor has not been fully resected. For patients with a curative total cystectomy, construction of a new ileal neobladder is possible.

E. Intravenous dextrose   Immediately following removal of a secretory PHEO/PGL, intravenous 5% dextrose should be infused at a constant rate of about 100 mL/h to prevent postoperative hypoglycemia that is otherwise frequently encountered.

F. Therapy for shock occurring after PHEO/PGL resection   Severe shock and cardiovascular collapse can occur immediately following ligation of the adrenal vein during resection of a PHEO, particularly in patients having norepinephrine-secreting tumors. Such hypotension may be due to desensitization of α_1-adrenergic receptors, persistence of antihypertensives, and low plasma volume. Preoperative preparation with CCBs or α-blockade plus intravenous hydration or blood transfusions reduces the risk of shock. Intravenous antihypertensives are held just prior to ligation of the adrenal vein. Treatment of shock consists of large volumes of intravenous saline or colloid. Intravenous norepinephrine is sometimes required in very high doses. In cases of post-resection catecholamine-resistant hypotension, intravenous low dose vasopressin administration may be efficacious, given as boluses of 0.08 U, followed by an intravenous continuous vasopressin infusion of 1.6 U/h.

Pregnancy and PHEO/PGL

PHEO/PGLs occur in about 1 in every 50,000 pregnancies and are often unrecognized antepartum. Such unsuspected PHEO/PGLs result in a maternal mortality of 40% and a fetal mortality of 56%. However, if the diagnosis is made antepartum, the mortality is much lower. Hypertension is often misdiagnosed as eclampsia or preeclampsia. Hypertensive crisis usually occurs during labor and can be associated with cardiac dysrhythmias or ARDS. Although maternal catecholamines do not cross the placenta, maternal hypertensive crisis is very dangerous for the fetus, causing uteroplacental insufficiency and fetal death.

Pregnant hypertensive patients are often treated with methyldopa that can cause false-positive testing for catecholamines by older fluorometric methodologies, but not by HPLC. Methyldopa does not cause interference with plasma or urine metanephrine measurements performed with MS/MS. Labetalol is often used to treat pregnant hypertensive women, but its use with PHEO/PGL is discouraged (discussed earlier).

During pregnancy, the localization of a PHEO in pregnancy is best done with MRI. As soon as a PHEO is diagnosed, α-blockade is commenced. **Phenoxybenzamine** is usually used. However, phenoxybenzamine crosses the placenta and accumulates in the fetus. After 26 days of maternal phenoxybenzamine therapy, cord blood levels in the newborn are 60% higher than the mother's serum levels. Therefore, some perinatal depression and hypotension may occur in newborns of mothers receiving phenoxybenzamine. Prazosin has an advantage for maternal treatment near term, since it is a short-acting selective α_1-adrenergic blocker and causes less newborn hypotension, compared to longer acting α-adrenergic blockers. However, chronic use of prazosin increases the risk of fetal demise. The starting dose of prazosin is 0.5 mg/d orally, increasing up to 10 mg orally twice daily if necessary.

There has been little experience with the use of CCBs to treat hypertension in pregnant women with PHEO. However, CCBs can be safely added to α-blockers during pregnancy and are not teratogenic in the first trimester. Therefore, nifedipine or nicardipine may be used to supplement or replace α-blockade as needed.

If possible, β-blockade should not be used at all during pregnancy. Propranolol crosses the placenta and can cause intrauterine growth restriction. Newborns of mothers taking propranolol at delivery exhibit bradycardia, respiratory depression, and hypoglycemia. Therefore, β-blockers should ideally be discontinued 48 hours prior to expected delivery. During delivery, serious atrial tachyarrhythmias should be controlled by a short infusion of esmolol, a β-blocker with a very short half-life.

Angiotensin converting enzyme (ACE) inhibitors should not be used during pregnancy, since their use in the second and third trimesters has been associated with fetal malformations, including skull hypoplasia, renal failure, limb and craniofacial deformation, lung hypoplasia, intrauterine growth retardation, patent ductus arteriosus, and death.

During the first 6 months of pregnancy, it is often possible to treat a woman with α-blockade, followed by laparoscopic resection of the tumor. Although the fetus usually survives, spontaneous abortion is common, despite a successful resection of the

tumor. If a PHEO is not discovered until the last trimester, treatment consists of α-blockade followed by elective cesarean delivery as early as feasible. Intravenous magnesium sulfate is a useful antihypertensive during surgery. Intravenous CCBs may be used to treat patients with hypertensive crisis caused by PHEO in pregnancy. The tumor is resected after the cesarean delivery. In the presence of an active PHEO, vaginal delivery should never be allowed, since life-threatening hypertensive crisis will predictably occur.

Pheochromocytoma-Induced Life-Threatening Complications: Cardiomyopathy, ARDS, and Multisystem Crisis

Life-threatening complications can occur in patients with PHEO/PGL in an idiosyncratic fashion and are not necessarily associated with hypertension.

1. **Cardiomyopathy** and attendant serious cardiac dysrhythmias often occur in patients with PHEO/PGL. It is also known as "catecholamine cardiomyopathy." Heart failure and shock can occur and can sometimes present with reverse ventricular activity, also known as "Takatsubo cardiomyopathy." "Takatsubo" is a Japanese term for a traditional octopus fishing pot, which the heart may resemble on imaging studies. Affected patients can present with life-threatening ventricular arrhythmias, cardiac rupture, systemic embolism, or shock due to cardiac pump failure. Serum BNP can be very high. The etiology for cardiomyopathy in PHEO/PGL has been ascribed to catecholamines, although circulating cytokines may also be contributory. Acute cardiomyopathy is potentially reversible after the tumor is removed or the patient is stabilized. Therefore, every effort must be made to salvage these patients, who may require mechanical circulatory support (MCS).

2. **ARDS** occurs in patients with PHEO/PGL and is not associated with unusually severe hypertension or particularly high plasma catecholamine levels, compared to other PHEO/PGLs. ARDS is more apt to occur in patients with proteinuria that may serve as a marker for patients at risk. Proteinuria and ARDS itself may be due to tumoral secretion of certain cytokines in the setting of catecholamine excess. ARDS can occur spontaneously, after major surgery, and after therapy with high-activity ^{131}I-MIBG in patients with metastatic disease. ARDS may accompany cardiomyopathy and can be mistaken for congestive heart failure or pneumonia. Most patients require intubation and respirator-assisted breathing with high oxygen supplementation. Some patients may require extracorporeal membrane oxygenation (ECMO). ARDS may progress to multisystem crisis.

3. **Multisystem crisis** can have manifestations such as ARDS, renal failure, hepatic failure, rhabdomyolysis, cardiomyopathy, shock, and disseminated intravascular coagulation. Multisystem crisis can occur spontaneously or following the administration of glucagon or corticosteroids. It can also occur following unrelated surgery or therapy with ^{131}I-MIBG. The mortality rate is extremely high despite intensive care. It has been hypothesized that ARDS and multiorgan crisis may be due to increased circulating cytokines, in addition to catecholamines.

Pathology of PHEO and PGL

On histopathology, PHEOs are extremely vascular tumors with neurosecretory granules. Central necrosis is often present. The cells may be arranged in nests (zellballen pattern), anastomosing cords (trabecular pattern), or a combination of both. Cells vary in size with pleomorphic and eccentric nuclei that are often large and bizarre in appearance. The cells exhibit immunofluorescence staining for CgA and synaptophysin.

No single characteristic of PHEO or PGL can determine whether a given tumor is malignant. Therefore, the definition of malignancy is based upon whether metastases are present. Metastases must be distinguished from additional PGLs by their location (liver, lung, bone) where sympathetic paraganglia are rare. Metastases must also be distinguished from intraperitoneal seeding, a phenomenon known as pheochromocytomatosis. Metastases can vary in virulence from relatively indolent to extremely aggressive (see discussion on malignant PHEO later).

Overall, about 26% of these tumors arise in patients with identifiable germline mutations. Individuals with no known family history of these tumors have about a 17% risk of harboring a known germline mutation. About 18% of cases develop in children. The earlier a tumor presents, the more likely that individual harbors a germline mutation (see discussion on genetics of PHEO and PGL, earlier).

Adrenal PHEOs and PGLs appear very similar on microscopy. PGLs are often large and arise near the adrenal, making the distinction particularly difficult based upon preoperative localization scans. But it is important to distinguish these two tumors because PGLs are more likely to metastasize. One way to distinguish these tumors preoperatively is to evaluate their secretions. Tumors that secrete epinephrine (or its metabolite, metanephrine) are predictably adrenal PHEO. However, tumors that secrete strictly norepinephrine (or its metabolite normetanephrine) may be either PHEO or PGL. Intraoperatively, the surgeon may be able to identify the adrenal gland as separate from the tumor. On pathology, it is often possible to visualize the adrenal cortex lying in close proximity to the PHEO or even arising out of the adrenal medulla. An intact adrenal gland may be included in the surgical specimen, indicating that the tumor was a juxta-adrenal PGL. On microscopy, PGLs may have visible nerve ganglia.

Composite PHEOs are rare tumors that exhibit histopathologic features of both PHEO and neuroblastoma. Such tumors have generally not recurred and have not exhibited *N-myc* amplification, which distinguishes them from typical neuroblastomas. Therefore, composite PHEO are considered to be a histological variant of PHEOs.

Metastatic Pheochromocytoma and Paraganglioma (Table 11–18)

No PHEO or PGL should be labeled *benign*. Histopathology cannot reliably determine whether a given tumor has metastasized. Such metastases can be microscopic and indolent, eluding detection with the most sensitive scanning and biochemical screening. Therefore, it is best to think of these tumors as either having

TABLE 11–18 Distribution of metastases in 50 cases of metastatic pheochromocytoma and paraganglioma.

Region of Metastasis	Percentage
Bones	82
Abdomen (nodes, peritoneum, local recurrence)	56
Lung parenchyma	36
Liver	30
Pelvis (soft tissue)	20
Mediastinum and lung hila	18
Lymph nodes (extra-abdominal) especially supraclavicular and inguinal	14
Chest wall	12
Muscle	6
Brain	0

Data from Gonias S, Goldsby R, Matthay KK, et al. Phase II study of high-dose [131I] metaiodobenzylguanidine therapy for patients with metastatic pheochromocytoma and paraganglioma. *J Clin Oncol*. 2009 Sep 1;27(25):4162-4168.

Note: Some cases of abdominal recurrence are peritoneal seeding (pheochromocytomatosis).

detectable metastases (metastatic PHEO) or having *no detectable* metastases.

Location: Metastases are evident at the time of diagnosis in about 10% of patients with an adrenal PHEO. Another 5% to 10% are found to have metastatic disease or local recurrence within 20 years. Extra-adrenal PGLs commonly metastasize. In a Mayo Clinic series of PGLs, 15% had local invasion and 21% had detectable distant metastases at the time of initial surgery, with an overall 36% risk of local or distant metastasis.

Genetics: The risk for detectable metastases is high for PHEOs/PGLs that arise in patients harboring a *SDHB* germline mutation, with this mutation being found in about 40% of metastatic PHEOs/PGLs. PHEOs/PGLs that arise in patients with *NF-1* germline mutations have a 12% risk of metastasis. PHEOs that arise in patients with *VHL* or *RET* germline mutations have a low (<5%) risk of metastasis.

It is conceivable that *all* PHEOs and PGLs metastasize as single cells but that such cells will only grow if certain genes are down-regulated and other genes are up-regulated. This concept is supported by genome-wide expression profiling of PHEO/PGLs. These profiles have identified candidate genes that are differentially expressed in tumors with detectable metastases versus those with no detectable metastases. Gene expression arrays of PHEOs/PGLs with detectable metastases have demonstrated that 5 genes are differentially up-regulated in these tumors.

Research in malignant PHEO/PGL has been hampered by the absence of a viable human cell line. However, a highly malignant mouse PHEO model has been developed in which a gene expression array has demonstrated the up-regulation of 8 genes and the down-regulation of 38 genes.

Other predictors of malignancy: The risk of PHEO/PGL recurrence is higher if there is extensive local invasion. One surgical observation is that tumors that are "stickier" and more difficult to dissect from adjacent tissue are more likely to recur or metastasize. Tumors are also more likely to metastasize if they are larger than 5 cm diameter, although about 20% of metastatic primary tumors have been smaller than 5 cm diameter. Primary PHEOs/PGLs as small as 1 cm diameter have been documented to metastasize. Tumors are also more likely to metastasize if they contain high levels of Ki-67, a protein expressed in proliferating cells that can be detected by the monoclonal antibody MIB-1 and quantified as a high MIB-1 score. Metastatic PHEOs/PGLs also have increased activity of telomerase. Tumors with high *c-myc* gene expression are more likely to be malignant. In one series, 50% of patients with malignant PHEO were found to have high serum levels of NSE, but in none of 13 patients in another series with benign PHEOs.

The differential diagnosis for apparent metastases includes, multicentric PGLs, second PHEOs, false-positive scanning, and intraperitoneal seeding of tumor (pheochromocytomatosis). Patients with familial forms of PHEO/PGL may develop other tumors associated with their mutation: medullary thyroid cancer (*RET*), renal cell cancer (*VHL, SDHx*), pituitary adenoma, GIST, pulmonary chondroma (SDHx). Other non-PHEO/PGL malignancies also appear to be more common. A series of 110 Swedish patients with PHEO/PGL, treated surgically, showed an unexpectedly high relative risk for developing non-PHEO/PGL malignancies (RR ≅ 2.0). Therefore, additional tumors should not be presumed to be metastases unless they have uptake on [123I]-MIBG or [18]FDA-PET scanning. Suspicious lesions without such uptake should be considered for biopsy.

Sites of metastasis (Table 11–18): Metastases from PHEOs or PGLs typically involve bones (82%), liver (30%), lungs (36%), lymph nodes, the contralateral adrenal, and sometimes muscle. The bones most frequently involved include vertebrae, pelvis and ischium, clavicles, cranium, proximal femurs, and humeri. Tibia, radius, and ulna are occasionally involved. Patients with metastases and an *SDHB* mutation have a higher prevalence of metastases involving long bones compared to those without the mutation. PHEO/PGL metastases have a proclivity for the skull where they may form a dumbbell-type lesion, sometimes being palpable as a soft cyst-like bump; they also may grow inside the skull to impinge upon the brain. Prevertebral PGLs may destroy adjacent vertebrae, and spinal cord compression may occur. Most bone metastases affect the cortical bone; they may be indolent, but are often osteolytic and cause progressive bone destruction. Other bone metastases primarily involve trabecular bone and marrow; such metastases are usually visible on MRI but may be invisible on CT. Metastases to lymph nodes outside the abdomen are most frequent in the supraclavicular and inguinal regions. Metastases to muscle are usually indolent. These tumors have not been reported to metastasize to brain, although metastases to the cranium and skull base may impinge upon the brain, pituitary, and cranial nerves.

Metastases usually secrete norepinephrine and normetanephrine. Some metastases secrete predominantly dopamine. Metastases rarely secrete epinephrine or metanephrine, with the exception of some metastases from epinephrine-secreting adrenal PHEOs. About 20% of sympathetic PGLs and their metastases do not secrete catecholamines or metanephrines, but most continue to secrete CgA, which becomes a valuable tumor marker.

Assessing the growth rate of PHEO/PGL metastases: Treatment can be tailored to the tumor's rate of growth. Knowledge of the growth rate of a patient's metastases may be obtained through close biochemical surveillance and serial volumetric imaging with CT or MRI. Patients who are asymptomatic with a few indolent osseous metastases may elect to receive bisphosphonate therapy and delay life-threatening chemotherapy or radioisotope therapy, as long as they remain under close surveillance. Even patients with a symptomatic osteolytic metastasis may elect to receive targeted therapy rather than systemic treatment if their overall tumor burden is low.

Surveillance: Malignancy is determined only by the presence of metastases. MRI or CT scanning may not detect small metastases within their field and will certainly not visualize metastases outside their field. The various radiolabeled imaging scans can also be negative in the presence of metastases. Therefore, following the resection of an apparently benign PHEO or PGL, long-term surveillance is required, since metastases may not become clinically apparent for years or decades.

Biochemical surveillance: Patients should be followed with repeated determinations for the tumor markers that were highest prior to resection of their primary PHEO/PGL. Repeat postoperative testing should be postponed until at least 2 to 4 weeks postoperative, and the patient is fully recovered from surgery. Unfortunately, some patients with unsuspected PHEO/PGL have incomplete or no preoperative testing prior to the surgical resection of their primary tumor. Biochemical screening for recurrence or metastases in such patients is best done with plasma-fractionated free metanephrines and fractionated catecholamines (with dopamine), along with a fasting serum CgA. While this survey of tumor markers is sensitive for PHEO/PGL recurrence, false-positive testing occurs commonly. When a PHEO/PGL tumor marker is only marginally elevated, the test should be repeated. Interpretation of elevated tumor markers should be done cautiously with the knowledge that adrenal PHEOs usually secrete both norepinephrine and epinephrine, and their metastases may sometimes continue to produce epinephrine, but more commonly produce norepinephrine and its metabolite normetanephrine. Extra-adrenal PGLs ordinarily produce only norepinephrine and normetanephrine and sometimes only CgA; their metastases do likewise. When such tumor markers are consistently elevated, repeat scanning is certainly warranted.

Scan surveillance: It must be kept in mind that scan surveillance is useful to detect not only recurrent or metastatic PHEO/PGL, but also to detect other malignancies to which these patients are prone. Unfortunately, the long-term repetitive use of any CT or radionuclide scan delivers excessive cumulative radiation exposure to the patient, increasing their lifetime risk of additional non-PHEO/PGL malignancies. Therefore, a reasonable combination of modalities must be used, relying upon biochemical surveillance for secretory sympathetic PHEO/PGLs (discussed earlier). Neck ultrasound is useful for nonsecretory HN-PGLs, but will not detect a jugulotympanic PGL. MRI is useful for detecting recurrent or de novo HN-PGLs. MRI is also useful for general scanning, but scanning the entire chest, abdomen, and pelvis usually requires a prolonged time in the scanner; it can also be problematic to obtain insurance preauthorization and to schedule a full-body MRI. *Rapid full-body MRI* has been developed and is available in certain tertiary referral centers. Rapid full-body MRI reduces the time for each image cut from several seconds to milliseconds. However, it is a screening scan, rather than diagnostic procedure and can miss smaller tumors. Also, full body MRI does not typically cover the extremities and does not detect metastases to the extremities.

Radionuclide scanning is advantageous in that the entire body may be included in the scan. Some kind of radionuclide scanning is indicated for patients with biochemical or clinical evidence of recurrent or metastatic PHEO/PGL. However, no radionuclide scan is 100% sensitive. PHEO/PGL metastases have variable avidity for ^{123}I-MIBG. Even when the primary tumor is avid for ^{123}I-MIBG, some or all of the metastases may not be visible on ^{123}I-MIBG scanning. This low sensitivity (57%) is seen for metastases that are deficient in norepinephrine transporter (NET) expression. In a given individual, some metastases may be avid for ^{123}I-MIBG, while others show virtually no uptake. When patients have a recurrence or progression of metastases after ^{131}I-MIBG therapy, metastases with less MIBG-avid may emerge or progress in size. When ^{123}I-MIBG imaging is negative, metastases may be detected with MRI or CT scanning. Metabolically active PHEO/PGL metastases are usually visible with ^{18}F-FDG-PET scanning, which has the additional advantage of being a whole-body scan with a sensitivity of about 76% for metastases. ^{18}F-FDA-PET has a sensitivity of about 78% for metastases. Somatostatin receptor scintigraphy or ^{68}Ga-DOTATATE-PET, will often detect metastases that are not visible with other scans.

Treatment for Patients with Recurrent or Metastatic PHEO and PGL

Patients with recurrent or metastatic PHEO/PGL must have individualized therapy and surveillance. They are usually considered for surgery, with the goal of either surgical cure or at least debulking. Some small metastases can be quite indolent, such that certain asymptomatic patients with a low and indolent tumor burden may be followed closely without treatment or treatment with less toxic modalities, such as denosumab or zoledronic acid for osseous metastases, and directed external beam radiation therapy for larger osteolytic metastases. In one series of 90 patients with metastatic PHEO/PGL, 9% had progression-free survival at 5 years.

A. General considerations *In vitro* studies have found that cultured PHEO cells are protected from cytotoxic insult by amitriptyline and fluoxetine, possibly through up-regulation of superoxide dismutase. Therefore, patients being treated for metastatic PHEO/PGL should probably not take tricyclic antidepressants or selective serotonin reuptake inhibitors, although there have been no clinical studies of their effect on survival. A clinical study of kindreds with *SDHD* germline mutations noted that individuals with this mutation who lived at higher elevations developed more PGLs earlier than their affected relatives living at sea level (the Netherlands). Therefore, it is possible that residing at higher altitude may stimulate the development of PHEO/PGL among

patients harboring *SDHD* germline mutations and perhaps other cluster 1 germline mutations with underlying pseudohypoxia (see Table 11–8). There is concern that chronic recurrent hypoxia from sleep apnea can trigger catecholamine release and might also stimulate tumor growth in susceptible patients with cluster 1 germline mutations. Therefore, screening for sleep apnea should be considered for affected patients who snore or have other risks for sleep apnea.

B. Surgery   It is usually best to resect the primary tumor as well as large metastases. This is especially true of secretory tumors that are causing hypertension and other symptoms that can be life-threatening. Even lung metastases may be resected. However, the decision about whether to resect metastases is a difficult one and must be based upon very thorough staging of the patient's tumor. Of course, when resecting secretory metastases, preoperative preparation is mandatory, and hypertension must be adequately controlled.

C. Chemotherapy   Due to the rarity of PHEO/PGL, there have been no large-scale clinical trials comparing available chemotherapies. However, there have been small series of patients and case reports from which to derive recommendations. Although chemotherapy can achieve remissions, no durable long-term remissions have been reported, such that lifetime chemotherapy is required. Therefore, when selecting chemotherapy, it is important to select a regimen that the patient can tolerate long term with a reasonable quality of life. Temozolomide is usually tolerated best. However, for aggressive metastases, it is best to induce a remission with either a tyrosine kinase inhibitor or cyclophosphamide, vincristine, and dacarbazine (CVD) combined chemotherapy (discussed later).

Temozolomide (TMZ): TMZ carries the advantage of either oral or intravenous administration on a daily basis for just 5 days monthly. Patients usually tolerate TMZ better than other chemotherapeutic regimens for long-term tumor suppression. However, TMZ causes nausea, and patients require prophylactic ondansetron and other supportive therapy during their treatment week. TMZ has reasonable anti-tumor effect in patients with metastatic PHEO/PGL, particularly those with *SDHB* germline mutations. In one study of 15 patients with metastatic PHEO/PGL (10 with *SDHB* germline mutations), treated with a mean dose of TMZ of 172 mg/m^2 daily for 5 days monthly, partial responses (PR) were observed in 5 patients, stable disease (SD) in 7 patients, and progressive disease (PD) in 3 patients. All 5 patients experiencing a PR had an *SDHB* mutation. If most metastases remain stable, the patient may continue TMZ, while limited break-through metastases are treated surgically or with external beam radiation therapy.

Cyclophosphamide, vincristine, dacarbazine (CVD): Combined chemotherapy with CVD is usually given intravenously over 2 days and the cycles repeated every 3 to 4 weeks, indefinitely. After controlling symptoms of catecholamine excess, cycles of CVD are administered as follows: cyclophosphamide 750 mg/m^2, vincristine 1.4 mg/m^2, and dacarbazine 600 mg/m^2 on day 1, followed by dacarbazine 600 mg/m^2 on day 2. The doses are adjusted according to the response and toxicity in each patient.

In a meta-analysis of 50 patients with metastatic PHEO/PGL treated with CVD, the tumor-size response rates have been: CR 4%; PR 37%; SD 14%; PD 45%. Catecholamine response rates have been: CR 14%; PR 40%; SD 20%; PD 26%.

When CVD chemotherapy is stopped, the tumors usually recur. Many patients cannot tolerate such a long-term regimen, due to fatigue, cytopenias, neuropathy, and other adverse reactions. However, some patients tolerate it reasonably well and may experience a complete biochemical remission. Once in remission, CVD cycles are continued at increased intervals, but not stopped.

Sunitinib: Partial remissions in metastatic PHEO have been reported with sunitinib, a tyrosine kinase inhibitor. Sunitinib is administered orally, usually in a dose of 50 mg daily in cycles of 4 weeks on, then 2 weeks off. However, a lower dose of 37.5 mg daily is also being used, since patients tend to tolerate the lower dosage better, and tumor growth has sometimes been documented during off weeks with the cycled regimen. The dosage may be adjusted in 12.5-mg increments according to response and toxicity. Sunitinib is metabolized in the liver by CYP3A4, so dose adjustments should be made for patients taking the wide variety of drugs that are inhibitors or inducers of CYP3A4. Sunitinib can cause serious adverse reactions, including heart failure, cardiac arrhythmias, marrow suppression, pancreatitis, hypo- or hyperthyroidism, nephrotic syndrome, and rhabdomyolysis with acute renal failure. Patients treated with sunitinib also commonly experience nausea, vomiting, diarrhea, hypertension, skin discoloration, mucositis, asthenia, dyspnea, myalgias, and arthralgias.

Adjuvant statin therapy: Certain lipophilic statins (lovastatin, fluvastatin, and simvastatin) inhibit the growth and migration of mouse PHEO cells and the more aggressive mouse PHEO tissue-derived cells *in vitro*. The effect appears to be mediated through inhibition of mitogen-activated kinase (MAPK) pathway. The MAPK pathway appears to play a role in certain human PHEO/PGL tumors with mutations in *K-RAS, RET, NF-1,* and *SDHB*. Although oral administration of these statins would not achieve adequate tumor levels to cause tumor cell apoptosis, the use of these statins is a promising therapeutic option as an adjuvant to chemotherapy. However, there have been no clinical trials to indicate whether this effect is clinically significant.

Potential therapeutic targets: ATP synthase (ATP5B) is an enzyme complex that is intracellular in most normal cells but is found on the surface of SDHB-associated PGLs and may promote tumor cell survival. Inhibition of tumoral ATP synthase with anti-ATP synthase antibodies and drugs that inhibit ATP synthase (eg, resveratrol) are possible future therapies against metastatic PHEO/PGL.

Triptolide, an inhibitor of nuclear factor-kappaB (NF-κB) increases the expression of norepinephrine transporter (NET) in PHEO cells and has increased the uptake of MIBG into mouse PHEO cells *in vitro*. Triptolide has also reduced the tumor burden in a metastatic PHEO animal model. Triptolide has serious clinical adverse effects; a better-tolerated prodrug (minnelide) is in early clinical trials for patients with metastatic GI tumors.

D. Bisphosphonates or denosumab   No controlled clinical trials have assessed the efficacy of bisphosphonates or

denosumab against osteolytic bone metastases from PGLs and PHEOs. However, bisphosphonates and denosumab have demonstrated effectiveness in other osteolytic solid tumors to reduce skeletal-related adverse events. Zoledronic acid is usually administered in doses of 4 to 5 mg every 1 to 2 months as an intravenous infusion to patients with osteolytic bone metastases. Patients unable to tolerate zoledronic acid may tolerate intravenous pamidronate. Denosumab is administered subcutaneously at initial doses of 60 mg every 1 to 2 months for patients with osteolytic bone metastases. Long-term therapy with either agent is associated with an increased risk for atypical subtrochanteric (chalk stick) femoral fractures, aseptic necrosis of the jaw, and metatarsal stress fractures.

E. Radiation therapy   When administered to patients with symptomatic spinal or cranial PHEO/PGL metastases, radiation therapy can reduce pain and produce neurologic improvement. Although conventional radiation therapy is usually administered, gamma knife can be given to smaller symptomatic bone metastases and to jugulotympanic PGLs. Conventional radiation therapy to large primary tumors or intra-abdominal metastases is not advisable, because it is usually ineffective and causes morbidity such as radiation enteritis and a proclivity to later surgical complications such as wound dehiscence, infections, and fistulas. However, small recurrent tumors can be treated with CyberKnife stereotactic radiosurgery. Surgical debulking of large abdominal or thoracic tumors (or other therapies) is usually preferable to radiation therapy. Radiation therapy to tumors reduces their uptake of ^{131}I-MIBG.

F. Arterial embolization and radiofrequency ablation   Before arterial embolization or radiofrequency ablation, patients with secretory PHEO/PGL must be fully prepared such that their blood pressure is near normal as described earlier. Pretreatment includes α-blockade and/or other measures such as β-blockade, CCBs, or metyrosine. Patients are monitored with arterial blood pressure transducers and given a central line before endotracheal general anesthesia. Anesthesia standby is necessary in case severe hypertension occurs, and it becomes necessary to administer intravenous antihypertensive drugs.

Arterial embolization has been used on rare occasions to reduce blood flow to PGLs and PHEOs, either in preparation for surgery or for inoperable cases. These tumors are usually very vascular and preoperative embolization may reduce intraoperative hemorrhage. Also, embolizing the tumor's blood supply may slow its growth. However, there have been no controlled clinical trials as to its effectiveness. A major potential risk of embolization is that of PHEO crisis. However, embolization has been used successfully on secretory tumors where the patient has been fully prepared with α-blockade and/or other measures. Localization arteriograms should use nonionic contrast.

Radiofrequency (RF) thermal ablation has been used successfully for patients with metastatic PHEO/PGL, particularly for liver and bone metastases. Most reported RF ablations of bone metastases have targeted rib or ischial/pelvic lesions. Before RF

ablations, the RF electrode(s) is guided into the tumor with ultrasound or CT guidance. Single electrodes may be used for small lesions, while metastases over 2.5 cm diameter usually require triple parallel cluster needle electrodes.

G. ^{131}I-metaiodobenzylguanidine (^{131}I-MIBG) (Figure 11–14) ^{131}I-MIBG is a treatment option for patients with metastatic or unresectable PHEO or PGL whose tumors are avid for the isotope. Benzylguanidine is a false neurotransmitter that resembles norepinephrine and is preferentially absorbed by PHEO/PGL tumors that express surface norepinephrine transporter 1 (NET 1) activity; it is tagged with ^{131}I to produce ^{131}I-MIBG. Only about 60% of metastatic or recurrent unresectable PHEO/PGLs have sufficient avidity for MIBG for ^{131}I-MIBG therapy to be potentially efficacious. Nonsecretory PHEO/PGLs frequently have sufficient MIBG to allow treatment. Pretreatment with nifedipine increased MIBG retention in 4/8 patients in one report. Some patients with good uptake of MIBG on diagnostic scanning have disappointingly poor uptake of large therapeutic doses of ^{131}I-MIBG, possibly caused by competitive inhibition by large amounts of nonradioactive ("carrier added") ^{127}I-MIBG that are present in most current formulations of ^{131}I-MIBG. A "no-carrier-added" formulation of ^{131}I-MIBG has been developed and is in clinical trials. Minnelide, a prodrug for an inhibitor of NF-κB has the potential for possibly increasing MIBG uptake into PHEO/PGL tumors (discussed later). Responses to ^{131}I-MIBG therapy occur over several months and continued decreases in tumor markers and tumor size may be observed for up to a year following therapy.

Protocol: Treatment protocols vary among institutions. Most currently employ repeated low-activity therapies of 100 to 250 mCi (3.7-9.25 GBq) or intermediate activity therapies of 250 to 500 mCi (9.25-18.5 GBq). High-activity ^{131}I-MIBG therapies over 500 mCi (18.5 GBq) have been employed for metastatic PHEO/PGL, but pose increased risks. ^{131}I-MIBG is administered intravenously over 30 to 90 minutes via a peripheral or central venous catheter. Following therapy with ^{131}I-MIBG, once background radiation has dissipated, a posttreatment whole-body scan is obtained.

Before and after ^{131}I-MIBG therapy, patients with an intact thyroid are premedicated with oral potassium iodide to reduce the risk of thyroid damage that could be caused by free ^{131}I generated through metabolism of ^{131}I-MIBG. The best-tolerated oral potassium iodide preparation is ThyroShield. Patients are all pretreated with non-phenothiazine antiemetics such as ondansetron; they remain hospitalized in lead-shielded rooms with radiation safety precautions until the emitted gamma radiation declines to acceptable levels, which usually requires about 4 to 9 days, depending upon the amount of activity infused and its uptake and retention by PHEO/PGL tumors. Repeated treatments may be required.

Responses: Complete remission (CR) or partial remission (PR), defined by RECIST (Response Evaluation Criteria in Solid Tumors), occur in about 22% of patients treated with ^{131}I-MIBG, while an additional 35% have minor responses (improvement in symptoms, tumor markers, and tumor size not meeting RECIST
FIGURE 11–14 Posttherapy scan 1 week after administration of 500 mCi ^{131}I-MIBG. Patient is a 22-year-old woman with a large unresectable PHEO in the left adrenal that has central hemorrhagic necrosis. There are widespread metastases to liver and bones. A metastasis to the left orbit has caused optic nerve compression and a visual field defect. A large metastasis to the left pelvis has caused pain and required prior external beam radiation therapy. **A.** Anterior image; **B.** Posterior image.

criteria for a PR); another 8% have stable disease (SD), at least temporarily. About one-third of patients fail to respond at all to ^{131}I-MIBG and experience progressive disease (PD) within a year after therapy. ^{131}I-MIBG therapy may improve 5-year survival, but controlled clinical trials are lacking.

Adverse reactions: Intermediate or high-activity ^{131}I-MIBG therapy predictably causes immediate lymphocytopenia, followed by some degree of platelet and neutrophil suppression that commences about 2.5 to 4 weeks after therapy. Therefore, patients must be observed and treated for any thrush or inguinal candidiasis and complete blood counts with platelet counts must be monitored after therapy. Platelet transfusions, red blood cell transfusions, or filgrastim may be required. High-activity therapy with ^{131}I-MIBG greater than 500 mCi (18.5 GBq) risks prolonged bone marrow suppression, requiring pretreatment peripheral blood stem cell harvesting with cryopreservation. High-activity ^{131}I-MIBG also increases radiation exposure to hospital personnel and is especially problematic if the patient develops complications and requires care in an intensive care unit without lead shielding.

Other adverse reactions to ^{131}I-MIBG therapy include nausea, occasional sialadenitis, transient hair loss, hypogonadism, and infertility. Also, ARDS and multisystem crisis have occurred in rare patients with proteinuria (a marker for this complication) after ^{131}I-MIBG therapy with activities greater than or equal to 500 mCi (18.5 GBq). Patients with PHEO/PGL who have any degree of proteinuria are at increased risk for ARDS and multisystem crisis, either spontaneously or after ^{131}I-MIBG or other

procedures. Patients with metastatic PHEO/PGL and proteinuria may be treated with repeated low-activity ^{131}I-MIBG therapies. Patients treated with ^{131}I-MIBG have an increased lifetime risk of second malignancies, particularly myelodysplastic syndrome (MDS) and leukemia. MDS and leukemia have occurred about 5 to 7 years after ^{131}I-MIBG, particularly in patients who have received cumulative activities greater than or equal to 1000 mCi (37 GBq).

Prognosis

The mortality rate for patients undergoing PHEO/PGL resection has dropped to under 3% due to improved medical preparation and surgical technique. Laparoscopic resections have reduced perioperative morbidity and shortened the length of hospitalization. However, even after complete resection of the PHEO/PGL, hypertension persists or recurs in 25% of patients. Recurrent hypertension is an indication for reevaluation for PHEO.

Following surgical resection of a PHEO/PGL without detectable metastases, patients have a 5-year survival rate of 96%. Risk factors for death from PHEO/PGL include tumor size over 5 cm, metastatic disease, and local tumor invasion. However, the long-term mortality rate is much higher than expected. In a Swedish long-term outcome study of 121 patients with PHEO/PGL, there was no perioperative mortality, but 50% of patients remained hypertensive postoperatively. Of the 121 patients, 42 died during an observation period averaging 15 years, versus an expected

24 deaths in an age-matched control population. Thus, their relative risk of mortality was increased 78% (RR 1.78). Of the 42 patients who died, 20 deaths were due to cardiovascular disease, 6 from associated neuroectodermal tumors, 5 from other malignancies, 7 from unrelated causes, and 4 from malignant PHEO/PGL.

Metastases are variably aggressive, between patients and within a given patient. Some metastases are quite indolent and may present clinically one or two decades after resection of the primary tumor. However, other metastases are exceptionally aggressive. Asymptomatic patients with only a few bone metastases tend to have the best prognosis, while those with a heavy burden of liver and lung metastases tend to have the most malignant disease.

Patients with metastatic PHEO/PGL who have appropriate surveillance and treatment now have average overall survival rates as follows: 5-year survival, 77%; 10-year survival, 62%; 20-year survival, 39%. *SDHB* germline mutations are found in about 81% of children with metastatic PHEOs/PGLs, compared to about 49% of adults. Genetics affects prognosis. Adults *SDHB* germline mutations tend to fare worse than patients with metastases from sporadic PHEO/PGL. However, children with metastatic PHEO/PGL associated with *SDHB* germline mutations tend to fare better than their adult counterparts.

PHEO and PGL: Postoperative Long-Term Surveillance

A preoperative ^{123}I-MIBG scan or other radionuclide scan (discussed earlier) is recommended for all patients with PHEO/PGL. Postoperative scanning is recommended for patients when there is any doubt about complete resection of an adrenal PHEO and for any patients with PGL or multiple tumors. The postoperative scan is usually obtained several months after surgery.

All patients with PHEOs/PGLs require lifetime postoperative surveillance. They require aggressive treatment of all cardiovascular risk factors, due to their increased long-term risk of death from cardiovascular causes. Additionally, patients should be tested for familial genetic syndromes and appropriately screened for associated malignancies (see Genetic Conditions Associated with Pheochromocytomas and Paragangliomas, see Tables 11–8 through 11–12). Persistent symptoms or hypertension can signify recurrence at the surgical site, seeding of the peritoneum, a contralateral PHEO, a PGL, or possibly metastatic disease. About 10% of adrenal PHEOs have metastasized at the time of diagnosis or soon postoperatively. However, occult metastatic disease is detected up to 20 years later in another 5%. Up to 35% of sympathetic PGLs have metastases at the time of diagnosis, particularly in patients harboring *SDHB* or fumarate hydratase (*FH*) germline mutations. Other patients develop multiple recurrent intra-abdominal tumors (pheochromocytomatosis) probably caused by tumor seeding that may occur spontaneously from the original tumor or during surgery.

Patients with secretory tumors are usually followed with plasma-fractionated free metanephrine determinations. Plasma-fractionated catecholamines and dopamine may also be obtained if they were predominantly secreted by the primary tumor. Serum CgA is a useful tumor marker for patients with PHEOs/PGLs

whose primary tumor secreted CgA and whose renal function is normal; elevated and rising levels of CgA usually indicate tumor recurrence or metastases (see CgA, discussed earlier). The type of biochemical follow-up is tailored to the individual patient. The first determination of postoperative plasma-fractionated free metanephrines is obtained at least 2 weeks after surgery, because catecholamine excretion often remains high for up to 10 days after successful surgery. Testing is obtained quarterly during the first year following surgery, then semiannually for at least 5 years. After 5 years, lifetime routine yearly physical examinations and biochemical screening are recommended, with immediate evaluation for recurrent PHEO/PGL if suspicious symptoms recur. For hypertensive patients, weekly home blood pressure monitoring is recommended for the first year postoperatively and monthly thereafter. A rising blood pressure or recurrence of symptoms should trigger a full workup for recurrent or metastatic PHEO/PGL.
